## Chronic Lymphocytic Leukemia

Mode of Presentation

Physical Findings

Laboratory Findings

Differential Diagnosis

Variants of CLL

Course of Disease and Cause of Death

Duration of Survival

Therapy

Principles of Management

Steroids

Alkylating Agents

Other Forms of Therapy

CHRONIC lymphocytic leukemia (CLL) is characterized by an excessive number of small lymphocytes in the blood and bone marrow. In most of the patients, excessive numbers of lymphocytes also are found in lymph nodes, spleen, liver, and other organs. The disease is unusual in persons younger than 30 years, becomes increasingly frequent with increasing age, and is approximately twice as frequent in males as in females (Chapter 46). Reports describing children with the disease in its characteristic form are exceedingly rare.<sup>12,28-29b</sup>

Chronic lymphocytic leukemia behaves less like a "cancer" than do any of the other diseases discussed in this section. Actually the use of the term "leukemia," from the standpoint of its impact on the patient, is unfortunate. The term "leukemia" is used to refer to disorders that are much more serious from the standpoint of morbidity and mortality

than is chronic lymphocytic leukemia. As discussed in Chapter 46, it is true that there is suggestive evidence that CLL represents the abnormal growth of a clone of "B"-type lymphocytes and thus, in that sense, it is a tumor. The lymphocytes accumulate in a variety of tissues and organs but do not produce detectable functional damage in most subjects. The prolonged survival and the failure of the survival curve to fit a log probability distribution,<sup>7</sup> however, are in contrast to most cancers. Many of the major complications reflect immunologic aberrancy. In 1914, Moreschi<sup>11</sup> noted that antibodies directed against the typhoid bacillus failed to appear in the serum of a patient with typhoid fever who also had CLL. Subsequent studies have suggested that failure to form circulating antibody is the primary cause of the frequent and severe infections observed in patients with CLL (Chapter 54).

It has been suggested<sup>18-23,56</sup> that there is a *benign form* and a *malignant form* of CLL, but studies indicate that in patients whose course seemed to be more rapid than in those who lived long following diagnosis, the diagnosis was probably made at a later stage of disease.<sup>7</sup>

### Mode of Presentation<sup>7,23,57</sup>

Approximately 25% of patients have no symptoms attributable to CLL at the time the diagnosis is made. These patients are found

to have blood lymphocytosis or enlarged lymph nodes or spleen on routine examination or during evaluation of apparently unrelated diseases. As with other forms of leukemia (Chapters 47 and 48) the most frequent complaint that causes the patient to consult a physician is fatigue or a sense of lack of well-being (Table 49-1). Less frequently, enlarged nodes or the development of an infection is the initial complaint (Table 49-1). Rarely, there are complaints of easy bruising or other bleeding problems. Weight loss is noted by some patients but this is rarely severe. Fever, in the absence of infection, rarely, if ever,<sup>6</sup> occurs in patients with CLL, in contrast to its frequent occurrence in those with the acute leukemias or the lymphomas (Chapter 54).

## Physical Findings

Enlarged lymph nodes are found in most patients, as is splenomegaly (Table 49-1). Hepatomegaly is detected in half of the patients, but sternal tenderness is much less frequent than in those with other forms of

leukemia (Table 49-1, Chapters 47 and 48). Lymph nodes usually are discrete, freely movable, and nontender, as in most forms of leukemia and lymphoma. Cervical and supraclavicular nodes are the ones most commonly enlarged, but palpably enlarged nodes in cervical, axillary, and inguinal areas also are detected in approximately half the patients at the time of diagnosis.<sup>7</sup> Splenomegaly usually is modest. The spleen extended less than 10 cm below the costal margin in 90% of our patients. It is firm and splenic infarction is much less common than in patients with CML or the acute leukemias. Less common manifestations observed in our series<sup>7</sup> were infiltration of tonsils (7%), masses presumed to be retroperitoneal nodes (2%), and skin infiltration (2%). Enlarged hilar lymph nodes or a widened mediastinum were detected on chest x ray in 5%. Pallor and ancillary signs of anemia rarely are prominent since anemia usually is mild at the time of diagnosis (page 1523). Similarly, because thrombocytopenia usually is mild, if present, petechiae or ecchymoses were noted in only 5%. Bacterial infection, most often pneumonia, with the

**Table 49-1. Signs, Symptoms and Blood Values in CLL at the Time of Diagnosis**

	Patients Surviving		All Patients

\*Fatigue, malaise or a vague sense of ill health

†Figure is probably exaggerated due to error in counting a minor cell population with a 200 cell differential count (Adapted from Boggs et al.<sup>7</sup>)

expected attendant signs, is a fairly frequent finding. A few patients, 5% of our series,<sup>7</sup> have no detectable physical abnormalities and the majority of such patients also are asymptomatic.

## Laboratory Findings

*Blood lymphocytes* do not exceed  $4.5 \times 10^9/l$  in normal subjects (Chapter 6). Patients with CLL may have as many as  $1000 \times 10^9/l$ , but the majority have less than  $100 \times 10^9/l$  when the diagnosis is made (Table 49-1), in contrast to those with CML in whom higher counts are usually found (Chapter 48). The exact level of blood lymphocyte

count at which one should consider the diagnosis of CLL is difficult to establish. When there has been opportunity to follow the development of CLL, the rise in blood lymphocytes has been very gradual but more or less continuous in the early stages (Fig. 49-1).<sup>20</sup> Cyclic fluctuations in numbers of blood lymphocytes may occur in untreated patients<sup>23</sup> and these may be very substantial, the count decreasing by as much as  $50 \times 10^9/l$  between visits to the physician. In certain untreated patients the lymphocyte count eventually becomes stabilized and may not rise further during months or years of observation.<sup>23</sup>

In most patients the average lymphocyte

Fig 49-1 The patient a 72 year old man had been hospitalized, because of psychiatric problems, at a Veterans Administration Hospital for 27 years when hematologic consultation was sought because of pneumonia and lymphocytosis. A routine hematocrit determination and leukocyte and differential counts had been done at yearly intervals. The number of blood lymphocytes had begun to increase eight years before the diagnosis of CLL was made at the time of the consultation. Small but enlarged cervical nodes and a palpable spleen tip were the only physical abnormalities other than the signs of pneumonia. Serum gamma globulin was abnormally low 0.4 g/dl. One year after the diagnosis of CLL was made the patient died from severe recurrent pneumonia.

has the *morphologic appearance* of the small lymphocyte seen in normal blood (Plate XXI). A minor population of abnormal-appearing lymphocytes often is present and in a few patients the average lymphocyte may be larger than normal and appear somewhat immature. Cells with deeply clefted nuclei (*Reiðer cells*) may predominate<sup>11</sup> and when the lymphocytes are abnormal it may be difficult to distinguish CLL from lymphosarcoma invading the blood or from leukemic reticuloendotheliosis (see Chapter 51). Cytoplasmic inclusions may be observed in lymphocytes from patients with CLL. In one study, crystalline inclusions that proved to be intimately associated with IgM  $\lambda$  were found in cells from four of 30 patients.<sup>15a</sup> Inclusions appearing as clear, geometric areas in Wright-stained smears that were made up of fibrillar bundles of unknown material have been noted,<sup>41a</sup> as have other globular, tubular, or rod-shaped inclusions.<sup>15a</sup> Some large inclusions have some of the characteristics of polyribosomes.<sup>1</sup> Normal lymphocytes may contain organelles that are membrane bound and stain positively for acid phosphatase, thus having characteristics of lysosomes; such structures are less frequent in lymphocytes from patients with CLL than in normal blood.<sup>18a</sup>

We were unable to correlate the frequency of unusual-appearing lymphocytes with any change in the clinical features of CLL in our series,<sup>7</sup> although others have suggested a more rapid course when numerous abnormal lymphocytes are present.<sup>3,54</sup> Ruptured leukocytes (basket cells) are common on blood smears of most patients with CLL but a satisfactory explanation for their presence has not been offered.

*Anemia* was present when the diagnosis was made in half of our patients (Table 49-1), but was usually mild, the *VPRC* being below 0.301/l in only 7% of the patients. The anemia usually is normochromic and normocytic and reticulocytes are normal or decreased in number. On occasion, severe hemolytic anemia is present at the time of diagnosis.<sup>1a,57</sup> Platelets are normal in number in more than half the patients (Table 49-1), and when

*thrombocytopenia* is present it is usually mild, platelet counts of less than  $50 \times 10^9/l$  being uncommon. *Neutrophil concentration* usually is normal, averaging  $6.0 \times 10^9/l$  in our series<sup>7</sup>; the incidence of neutropenia is probably overestimated in Table 49-1 by virtue of the distributional error for a minor leukocyte population in differential counts.

*Bone marrow aspiration or biopsy* is of little or no help in making a diagnosis of CLL when striking degrees of blood lymphocytosis are present. If blood lymphocytes are increased only to a slight degree, eg, 5.0 to  $10.0^9/l$ , the finding of disproportionately increased numbers in bone marrow may provide some diagnostic support. However, almost all patients with symptomatic CLL have in excess of  $10.0 \times 10^9/l$  when the diagnosis is made.<sup>7</sup> In patients with palpably enlarged lymphoid tissue but without blood lymphocytosis, marrow examination may disclose lymphosarcoma (Chapter 51). Biopsy discloses a hypercellular specimen with either focal or diffuse infiltration with lymphocytes. It must be kept in mind that smears of aspirated marrow also contain cells from the blood so that the percentage of marrow lymphocytes may be overestimated if blood lymphocyte counts are high. Rarely, normal percentages of marrow lymphocytes have been noted when blood lymphocytosis was present.<sup>57</sup>

Serum *uric acid* usually is normal and uric acid excretion rates often are normal.<sup>53</sup> *Immunoglobulin levels* are decreased in many patients (pages 1525 and 1526). Serum *albumin* and alpha and beta globulin levels usually are within normal limits.<sup>5</sup> Serum electrophoresis on acrylamide gel, a procedure yielding some 25 separate protein bands in normal sera, reveals the loss or marked decrease of a normal band, the "P" band, which moves near transferrin, and also shows a new "X" band which moves even closer to transferrin than "P."<sup>65</sup> The significance and nature of this change must await further study, but the absence of a similar change in lymphosarcoma (LSa) suggests that this may be a specific finding in CLL. Excessive excretion of urinary pseudouridine is present in most patients with CLL.<sup>64</sup>

## Differential Diagnosis

Diagnostic problems are uncommon in CLL since other causes of prolonged lymphocytosis are rare. Recovery phases of infection, especially chronic infections such as tuberculosis, may be accompanied by modest degrees of lymphocytosis.<sup>25,47,68</sup> Transient, but fairly profound increases in small lymphocytes in the blood may accompany pertussis or infectious lymphocytosis, but these usually are diseases of children or young adults. Striking lymphocytosis was reported in a patient with pernicious anemia, thought not to be due to coexistent CLL.<sup>2</sup> As reported by Sagoe,<sup>52</sup> "tropical splenomegaly" (page 1411) may mimic CLL to a greater extent than any other disease. This disease of unknown cause responds to therapy with proguanil, an antimalarial compound. Sagoe reported a series of patients with seemingly identical signs and symptoms, some of whom responded to proguanil therapy but others did not. Three of 11 nonresponders eventually developed typical CLL. In responders blood lymphocytosis was as high as  $35.0 \times 10^9/l$  and there was lymphocytic infiltration of the liver and marked splenomegaly. Responders differed from nonresponders in IgM levels, which were high in the former and low in the latter, and in lymphocyte blastogenic response to phytohemagglutinin, which was normal in responders but abnormal in 10 of 11 nonresponders.

Infectious mononucleosis and other viral illnesses that produce an infectious mononucleosis-like blood picture (Chapter 43) usually are found in children or young adults and should be easily distinguished from CLL by the morphologic appearance of the cells and the attendant signs and symptoms.

Basically, if lymphocytosis persists for some months in a middle-aged or elderly patient in whom no symptoms and signs are present or in whom symptoms and signs suggest CLL, the diagnosis can be made. However, since therapy at this stage is probably ill advised (page 1529) there is no urgency in making a firm diagnosis. Biopsy of enlarged

lymph nodes, marrow examination, or other histologic study may or may not reassure the physician in the correctness of his diagnosis but are unnecessary and do not benefit the patient.

## Variants of CLL

Most physicians will not make the diagnosis of CLL unless an excessive number of lymphocytes is present in the patient's blood. Others recognize an "aleukemic" form in which excessive lymphocytes are present in marrow but not in the blood.<sup>23</sup> This form is perhaps better designated as *lymphocytic lymphosarcoma (LSa) of bone marrow* (Chapter 51). There is evidence that the prognosis of such patients is inferior to that of patients with CLL.<sup>7,48</sup> For example, among patients with "CLL" whose leukocyte counts were less than  $10.0 \times 10^9/l$  at the time of diagnosis, 5-year survival was less than half that observed in the entire group.<sup>70</sup> The pathologic changes in lymph nodes, spleen, and liver appear identical in CLL and in lymphocytic LSa.<sup>20,45</sup>

Patients may have skin infiltration when first seen (Fig. 49-2) and later develop lymphocytosis, a condition that has been referred to as *erythrodermia* or *Sézary's syndrome* (Chapter 51). Also, a CLL-like blood picture may develop during the course of lymphosarcoma; this is termed *leukolymphosarcoma* (Chapter 51). A few patients with otherwise typical ALL have moderately mature-looking lymphocytes (Chapter 47). Rarely, abnormal lymphocytic manifestations defy classification. We observed one man, 62 years of age, who had large lymphoblastic-appearing cells in his blood (Fig. 49-3), with counts ranging as high as  $300.0 \times 10^9/l$  for at least 5½ years and possibly even twice that long. This patient had none of the usual features of ALL and none of the immunologic deficits or aberrancies of CLL.

## Course of Disease and Cause of Death

As evidenced by the very prolonged survival that is possible in patients with CLL

Fig. 49-2. Skin lesions in a patient with chronic lymphocytic leukemia, with an inflammatory reaction superimposed on leukemia cuts. On a base of indurated skin there is a brownish encrustation due to the oozing of a pink fluid. There was marked general glandular enlargement, splenomegaly, and a leukocytosis of  $200 \times 10^9/l$  with 93% lymphocytes.

Fig. 49-3. Blood cells of a patient with "chronic lymphoblastic leukemia." The lymphoblasts were present continuously in large numbers in the blood for at least 5½ and perhaps 11 years before the patient (CM 5374) died in 1962. An increased leukocyte count had been noted in 1951 at a time when the patient suffered from fatigue and foot drop. In 1956, fever of unknown cause developed and lymphoblasts were found in the blood smear and were noted on all subsequent examinations until the patient's death. Exploratory laparotomy with liver and lymph node biopsy and splenectomy showed little abnormality and while clumps of blasts were present on aspiration of marrow, abundant normal cells were also present. Lymphadenopathy never developed but when more than  $300 \times 10^9$  lymphoblasts/l were present, moderate anemia and thrombocytopenia were noted. At this stage, sequential therapeutic trials of prednisone, 6-MP, and methotrexate were of no benefit. The patient died at home of unknown causes at age 67. Since his course failed to fit into the syndromes of either ALL, CLL, or lymphosarcoma the diagnosis "chronic lymphoblastic leukemia" was made.

(page 1527) the course often is quite benign and many patients remain asymptomatic for years.<sup>7,67</sup> Since this is a disease of the elderly, unrelated but coexisting disease is a relatively common cause of death (Table 49-2).<sup>7,20b,57</sup> Death attributable to CLL usually is caused by uncontrolled infection<sup>7,20b</sup> (Table 49-2). Unless myelotoxic therapy has induced neutropenia, infection is usually attributable to deficient antibody production (page 1520, Chapters 46 and 54). Patients without extensive evidence of disease may have hypogammaglobulinemia (Fig. 49-1), and development of infection may be the first evidence of disease (Table 49-1); without vigorous and appropriate antibiotic therapy the outcome may be fatal. Because of susceptibility to infection, vaccination with living organisms, such as smallpox, is contraindicated (Chapter 54). Since fever due to the disease itself is exceedingly rare<sup>6,7</sup> the appearance of fever in persons with CLL should be assumed to indicate the presence of infection. It has been stated, without documentation, that fever occurs due to disease in "aggressive" CLL, especially when retroperitoneal nodes are present.<sup>51</sup> This has not been our experience; the possibility of obscure infection may be difficult to rule out. In general, the antibody deficit and the frequency of infections increase with duration of disease (Chapter 54).

*Transformation into an acute phase*, the usual cause of death in CML (Chapter 48), is exceedingly rare in CLL, if it ever occurs. Transition from a picture of LSA to CLL and then to ALL is occasionally observed (Chapter 51), but we have never encountered a patient with an initial diagnosis of CLL who developed an ALL-like picture. There are a few reports<sup>38,39</sup> suggesting such a transformation, but the cases of CLL usually have been atypical.<sup>38</sup> Other reports<sup>43</sup> suggest coexistence of two diseases rather than transition. A search of 340 cases of CLL revealed a terminal picture of acute leukemia in two patients,<sup>39</sup> one AML and one ALL. This was slightly but not significantly above the expected frequency of acute leukemia in the general population. There are at least two

**Table 49-2. Cause of Death in 50 Patients with CLL**

	Percent
Death apparently related to CLL	54
Due to infection	46
Due to thrombocytopenia	4
Meningeal infiltration and meningitis	2
Hemolytic anemia	2
Death related to complications of therapy*	16
Death apparently unrelated to CLL†	30

\*Hemorrhage or infection during development of profound thrombocytopenia and/or neutropenia following therapy with nitrogen mustard (4 patients) urethane (1 patient) or chlorambucil (1 patient) serum hepatitis (1 patient) and acute tubular necrosis following transfusion (1 patient).

†Myocardial infarction (3 patients) congestive heart failure without anemia (2 patients) thrombophlebitis and pulmonary embolism (2 patients), diabetes (2 patients) and one each with prostatic carcinoma bile duct carcinoma, Hodgkin's disease, perforated peptic ulcer, cerebral thrombosis, and an auto accident (Adapted from Boggs et al.<sup>7</sup>)

reports of AML developing in patients with CLL after prolonged therapy with chlorambucil as well as at least 17 after <sup>32</sup>P therapy.<sup>43</sup> These developments are thought to be related to the leukemogenic effects of the therapeutic agents used, rather than to natural transitions. One of our patients developed Hodgkin's disease, an occurrence also reported by others,<sup>64</sup> but whether this was due to chance or was a meaningful association cannot be determined.

*Inappropriate antibody formation* appears to be responsible for many serious complications in CLL. Coombs'-positive hemolytic anemia of severe degree complicates the course of from 10 to 20% of patients<sup>57</sup> and a platelet consumption syndrome similar in its manifestations to that of autoimmune thrombocytopenia (Chapter 34) is seen in a few.<sup>7,19</sup> The diagnosis and management of these complications are discussed in Chapter 54. Other bizarre immune responses, such as exaggerated delayed hypersensitivity reactions to mosquito bites, may develop.<sup>63</sup> The appearance of cryoglobulinemia with symptomatic cold urticaria<sup>16</sup> or of cryofibrinogenemia<sup>32</sup> during the course of CLL might

be included in this category. Monoclonal serum protein spikes may be observed in as many as 5% of patients with CLL<sup>12,50</sup> and a fairly typical picture of myeloma including marked marrow plasmacytosis and bone lesions has been a terminal complication in patients observed by us and others.<sup>61</sup>

*Carcinoma* is considered by some<sup>57</sup> to be more common in CLL patients than would be expected on statistical grounds, but other series in which the incidence in association with CLL was compared with age-matched controls did not disclose an excess occurrence of other tumors (Chapter 46).

Severe anemia, thrombocytopenia, and/or neutropenia, presumably due to *marrow failure* since no evidence of excessive cellular destruction is present, may develop eventually.

### Duration of Survival

The average patient in our series lived for six years after the diagnosis had been made, as calculated by actuarial survival methods (Fig. 49-4).<sup>7</sup> These survival figures are virtually identical to those noted by Osgood,<sup>42</sup> slightly lower than the selected series of Hill et al.<sup>30</sup> and probably not significantly higher than those reported in certain other relatively recently reported series.<sup>27,29b,31</sup> Zippin et al.<sup>70</sup> found a median survival of slightly more than four years in 839 patients from 24 hospitals in whom the diagnosis was made between 1955 and 1964. In older series,<sup>4,35,40,60</sup> shorter average survival was reported, but in these studies patients who were still alive usually were excluded. Analysis of our series in the same manner that Bethell<sup>4</sup> and Leavell<sup>35</sup> utilized in analyzing theirs revealed a slightly but not statistically significant longer survival in patients treated between 1945 and 1964 as compared to those treated before 1940.<sup>7</sup> Direct comparison of survival in various series has little meaning, however, because of the influence of uncontrolled selective factors. Not only does treatment differ from series to series but the population seen by a referral center may differ from that of a general hospital. For example, the series of

patients analyzed by Zippin et al.<sup>70</sup> tended to be older than our own.<sup>7</sup> While exact figures cannot be given it seems likely that average survival from diagnosis of CLL is from four to six years.

Very prolonged survival is possible. The longest survivor in our series died of pneumonia at age 79, 24 years after a diagnosis of CLL was made. Survival for as long as 35 years has been reported.<sup>44</sup> Since many patients die of unrelated causes (Table 49-2) the course of CLL is more accurately reflected in survival curves that exclude death from unrelated causes (Fig. 49-4)—“disease-oriented” versus “patient-oriented” survival.<sup>7</sup> When so calculated, median survival from the time of diagnosis was nine years in our patients.<sup>7</sup>

The duration of survival in part depends upon the severity of the disease at the time of diagnosis. Patients who survived for more than five years had less severe signs and symptoms and less abnormal laboratory findings than did those who survived for less than five years (Table 49-1). However, since members of the latter group were older and had had symptoms for a longer period before diagnosis (Table 49-1) than did the longer survivors it appeared to us that the more severe manifestations at the time of diagnosis reflected a longer period of preexisting, unrecognized disease rather than the existence of more “aggressive” disease.<sup>7</sup> Specific factors may be correlated with duration of survival. Young patients developing CLL tend to live longer after the diagnosis is made than older ones,<sup>7,35,42,70</sup> in contrast to the clinical impression of some.<sup>18</sup> Females may live longer than males.<sup>42,70</sup> An inverse relationship between the height of the leukocyte count and duration of survival was found in some<sup>7,35</sup> but not all<sup>4,42,57</sup> studies. In one study, patients with leukocyte counts of less than  $25.0 \times 10^9/l$  or of more than  $50.0 \times 10^9/l$  survived for a shorter time than did those whose initial count was between these two figures.<sup>70</sup> Anemia<sup>7,35</sup> and thrombocytopenia<sup>7</sup> are poor prognostic signs. Actually, although specific correlations are poor, there is a direct relationship between survival and

Fig 49-4 Survival of 130 patients with chronic lymphocytic leukemia from onset of symptoms (A) or from time of diagnosis (B), based on deaths from all causes and deaths related to the leukemia (From Boggs et al \* courtesy of the authors and American Journal of Medicine)

the presence of symptoms, signs, and abnormal laboratory findings in patients with CLL.<sup>7,23,57,70</sup> As shown in Table 49-1, patients surviving for the shortest time had more severe disease as judged by any parameter than did those surviving for longer periods. However, certain complications, such as hemolytic anemia<sup>37</sup> or skin infiltration,<sup>35</sup> may have no prognostic significance if proper treatment is given. Scoring methods to pre-

dict survival have been suggested.<sup>49</sup> In general, in the aggregate the more evidence of disease at the time of diagnosis, the shorter is the survival time. Nevertheless, individual variation is so great that such predictions are of little individual benefit. We have observed patients who, when first examined, had extensive disease, including anemia and thrombocytopenia, and lived more than 10 years. Others with minimal evidence of disease died

in less than five years of recurrent infection.

If those who have minimal disease when first seen by the physician are patients in whom the diagnosis is made at an early stage rather than those having a benign form of disease, then the survival of those in whom the diagnosis was made before symptoms developed may more accurately reflect the true course of the disease. Members of such a group may live for an average of at least 10 years (Fig. 49-5).

## Therapy

### Principles of Management

Whether antileukemic therapy favorably influences survival is moot. The slight increase in survival of our patients,<sup>7</sup> who were treated primarily with alkylating agents and

steroids or not at all, and of those of Osgood,<sup>42</sup> who were treated with  $^{32}\text{P}$ , as compared to Leavell's<sup>35</sup> and Bethell's<sup>4</sup> patients, who were treated primarily by x-irradiation, easily could be accounted for by the availability of therapy for infection and hemolytic anemia in our and in Osgood's series. Survival figures for a large untreated series are not available, but in 1924 Minot and Isaacs<sup>40</sup> reported no difference in survival of a small group treated by irradiation as compared to an untreated group. Osgood's patients<sup>42</sup> received more vigorous therapy than did ours,<sup>7</sup> suggesting that vigorous antileukemic therapy may not prolong survival. In a controlled trial, patients treated with  $^{32}\text{P}$  lived for a shorter period than did those treated with chlorambucil or triethylenemelamine.<sup>31</sup> However, the survival period of this  $^{32}\text{P}$ -treated group was significantly shorter

Fig 49-5 Survival of 31 patients in whom the diagnosis of CLL was made before symptoms attributable to the disease had developed (From Boggs et al,<sup>7</sup> courtesy of the authors and American Journal of Medicine)

than that of the group treated with  $^{32}\text{P}$  by Osgood<sup>42</sup> and the remainder survived no longer than did members of other series.<sup>7,42</sup> Thus, the correct conclusion from Huguley's study<sup>31</sup> may be that  $^{32}\text{P}$  shortened life rather than that life was prolonged by chlorambucil or triethylenemelamine. We cannot agree with the conclusion reached by some<sup>50</sup> that life clearly is prolonged by therapy and that therapy should be employed routinely in most patients. In an uncontrolled study, longer survival was noted in patients who were not treated within four months of diagnosis, as compared with those who were.<sup>70</sup>

If, as suggested, antileukemic therapy fails to prolong survival, then the use of such therapy must be examined with respect to its effects upon morbidity. The proper use of adjunctive therapy in patients with complications (Chapter 54), especially infection, hemolytic anemia, and obstructive masses, may be more important than systemic antileukemic therapy. Certainly one cannot favorably influence morbidity in asymptomatic patients; consequently, it is our practice to observe such patients as well as those with minimal symptoms and give no therapy. In contrast to the numerous controlled studies of therapy, including comparison of antileukemic drugs and placebos, which have been carried out in acute leukemia (Chapter 47), reports of studies that systematically compare the effect of routine antileukemic therapy to watchful waiting in CLL have not as yet been published. Consequently, indications for therapy are difficult to define unless complications such as hemolytic anemia (Chapter 54) are present. However, a trial of therapy is certainly in order if symptoms become increasingly troublesome due to increasing anemia or perhaps due to the increased metabolic demands of large tumor masses.

If treatment is decided upon, several forms of therapy are available.

#### Steroids

Virtually all patients who are treated with 0.5 to 1.0 mg of prednisone per kilogram of

Table 49-3. Effect of Therapy on CLL

	Favorable Effect (%)	Unfavorable Effect <sup>*</sup> (%)
<b>Chlorambucil or triethyl- enemelamine (100 courses)</b>		
Blood lymphocytosis	80	0
Lymph node, liver and spleen size	55	10
Anemia	14	23
Thrombocytopenia	4	4
Neutropenia	2	20
<b>Steroids (29 courses)</b>		
Blood lymphocytosis	17	0
Lymph node, liver and spleen size	68	0
Anemia	83	0
Thrombocytopenia	48	0

<sup>\*</sup>Enlargement of nodes or other tissues during therapy or reduction of red cells, platelets, or neutrophils persisting for more than six weeks after therapy was stopped (Adapted from Boggs et al.<sup>71</sup>)

body weight per day report significant symptomatic improvement.<sup>7,55</sup> Furthermore, significant regression of the size of lymph nodes and of the spleen as well as lessening of anemia and thrombocytopenia usually are observed (Table 49-3). In patients receiving steroid therapy, as lymph nodes and spleen decrease in size the blood lymphocyte concentration usually increases, doubling and even tripling from pretreatment values.<sup>55</sup> However, after some weeks of therapy, lymphocyte concentration begins to fall and may then decline to below pretreatment values.<sup>7,55</sup> Thus, from examination of subjective and objective antileukemic effects, prednisone would appear to be an excellent drug. However, in a controlled, "cross-over" type of study the frequency of life-threatening infections in patients with CLL was suggestively higher during a three-month period of prednisone therapy as compared to a three-month control period.<sup>53</sup> Since infection is the major cause of death and since infections in steroid-treated patients with a variety of diseases are unusually severe, this side effect of prednisone limits its usefulness in patients with CLL. Nevertheless, when severe anemia

requiring regular transfusion develops even in the absence of hemolysis, response to steroids may be noted and long-term therapy may be justified despite the risk of infection.<sup>22</sup> In some patients this form of anemia also responds to androgen therapy (Chapter 54). The use of steroids in controlling hemolysis and severe thrombocytopenia is discussed in Chapter 54. Trials of intermittent as compared with continuous steroid therapy<sup>10</sup> have been too limited to evaluate with respect to antileukemic effect as compared with toxicity.

### Alkylating Agents

During early trials of *nitrogen mustard* it became evident that CLL patients treated with this drug were more likely to develop severe and even fatal (Table 49-2) pancytopenia than were patients with Hodgkin's disease given comparable doses. Consequently, the orally administered drugs have been preferred as their toxic manifestations usually can be controlled by discontinuing their use at the first evidence of marrow depression. *Chlorambucil*<sup>17,20,21</sup> is probably the drug most

used in the treatment of patients with CLL (Fig. 49-6). The results of a controlled trial suggested that it was slightly superior to busulfan in this disease.<sup>51</sup> *Cyclophosphamide* also has been used widely in treating patients with CLL and differs little, if at all, from chlorambucil in its effects.<sup>34</sup> Another alkylating agent, *elderfield pyrimidine mustard*, may be superior to either chlorambucil or cyclophosphamide for CLL therapy.<sup>37</sup> Chlorambucil is given in a daily dosage of 0.1 to 0.2 mg/kg or 0.4 mg/kg biweekly<sup>34a</sup>; cyclophosphamide, 1 to 2 mg/kg daily. The level of erythrocytes, platelets, and neutrophils must be carefully monitored and therapy should be discontinued with any evidence of its decline. Unfortunately, the numbers of these cells often are depressed for prolonged periods after stopping therapy and do not readily return to normal levels (Table 49-3). Somewhat better results than those cited in the table have been reported by others, at least during the first course of chemotherapy.<sup>20,24</sup> This is in contrast to other forms of leukemia; eg, anemia regularly improves with chemotherapy in patients with CML. The reason why normal blood cells respond

Fig. 49-6. Course of a patient with chronic lymphocytic leukemia who had marked leukocytosis but only slight anemia and thrombocytopenia and was treated at long intervals with chlorambucil

less consistently to alkylating agents given to patients with CLL than to patients with CML is not known.

It has been suggested, but in no sense proved, that administration of alkylating agents or irradiation therapy may precipitate autoimmune hemolytic anemia as well as other hyperimmune phenomena.<sup>36,69</sup> Most patients report symptomatic improvement during alkylating agent therapy and in most a decrease in the number of blood lymphocytes, usually accompanied by decrease in the size of lymph nodes and spleen, is observed (Table 49-3). The end point of a course of therapy is difficult to assign since depression of normal blood cells usually develops before blood lymphocytes return to normal or spleen and lymph node enlargement disappears. As to maintenance therapy with small doses of drug given daily, advocated by some, a controlled study showed no obvious advantage of this therapy over intermittent therapy.<sup>50</sup>

### Other Forms of Therapy

**Irradiation** of the spleen and other areas of enlarged lymphoid tissue,<sup>16,40</sup> extracorporeal irradiation of the blood,<sup>21,38,39</sup> irradiation of retroperitoneal nodes by introducing radioactive substances into lymphatics of the feet,<sup>15</sup> attempts to concentrate radioactive material in reticuloendothelial tissue by giving it in colloidal form,<sup>30</sup> spaced doses of whole-body irradiation using <sup>32</sup>P<sup>31,42,57</sup> or x-irradiation,<sup>33</sup> and a variety of drugs<sup>51,56</sup> will all reduce the total number of lymphocytes as will antilymphocyte serum (Chapter 55). Leukapheresis<sup>17</sup> and thoracic duct drainage<sup>9</sup> reduce blood lymphocyte levels and may induce a decrease in the size of lymph nodes and spleen.

**Complete remission**, as defined for acute leukemia with no residual evidence of disease, is most unusual in CLL.<sup>7,14,29</sup> In the only patient in whom we have observed a complete remission, the remission may have occurred spontaneously,<sup>14</sup> as it has in a few other patients.<sup>14,29</sup> The report<sup>62</sup> of improvement in CLL as polycythemia vera developed suggests that there are natural means of sup-

pressing the manifestations of CLL. Some authors have chosen to use a definition of remission that allows moderately severe thrombocytopenia and anemia to be present.<sup>33</sup> No form of therapy has been reported that leads to a rise in serum immunoglobulins, the factor that seems to be most responsible for infection—the major cause of death in CLL patients. The aberrant blastogenic response of blood lymphocytes cultured with phytohemagglutinin (PHA) changes toward normal when blood lymphocyte concentration has returned toward normal following therapy.<sup>8</sup> However, there is no evidence that serum gamma globulin levels and response to antigenic stimulation or frequency of infection are improved favorably by therapy.

Thus, it is difficult to be dogmatic concerning the treatment of patients with CLL. *Since evidence of benefit from therapy is equivocal, we prefer to allow many of our patients to remain untreated for prolonged periods, except for vigorous treatment when complications occur (Chapter 54).* When systemic chemotherapy is employed, a course of 40 mg, or less, of prednisone per day is given for four to six weeks and chlorambucil or cyclophosphamide is then added and the administration of prednisone is stopped. Alternatively, prednisone and an alkylating agent may be given in combination rather than sequentially. In a controlled clinical trial, chlorambucil, 6 mg/day, plus prednisone, 30 mg/day, for six weeks was found to be superior to chlorambucil alone with respect to tumor reduction and effect on levels of normal blood cells.<sup>29a</sup> The blood must be monitored, however, to make certain that more good than harm is being accomplished. As yet to be evaluated is intermittent therapy with cyclophosphamide and vincristine intravenously and prednisone orally (COP, Chapter 51). In general, in case of doubt, it is best to withhold therapy, thereby at least avoiding toxic injury induced by the therapeutic agent.

*To sum up*, the least important indication for therapy in CLL is the number of lymphocytes. Also of low importance are adenopathy and splenomegaly, unless these are very great and physically troublesome. Reas-

surance that these in themselves are not harmful or of serious prognostic significance often suffices. Of importance, on the other hand, are the development of anemia, thrombocytopenia (if severe), and impairment of immune defense mechanisms.

background. Three relatively recent developments are of particular significance: (1) realization that cure of the disease is a reasonable goal in many patients; (2) recognition of the prognostic implications of various histologic classes of HD; and (3) appreciation of the prognostic importance of the clinical extent of disease at the time of diagnosis.

### Classification of Hodgkin's Disease

At most treatment centers, two systems of classifying the disease are applied to each patient, one based upon the histologic appearance of the excised tumor (histologic classification) and the other determined by a thorough evaluation of the extent and location of tumor (clinical classification).

#### Histologic Classification

Hodgkin's disease is distinguished from other lymphomas by certain large, binucleate cells having vesicular nuclei and prominent eosinophilic nucleoli. These cells, called Reed-Sternberg cells, are scattered irregularly throughout Hodgkin's infiltrate. Although Reed-Sternberg cells<sup>103</sup> may be seen occasionally in hyperplastic or inflammatory lesions of lymph nodes, they remain the most reliable histologic marker of Hodgkin's disease, in the absence of which the diagnosis should not be made.

**H**ODGKIN's disease (HD) is a tumor of lymphoid tissue that is recognized by distinctive histologic changes in excised tissue. Although it can occur in persons of any age (Chapter 46), it is most commonly seen in young adults and is more common in males than in females (Chapter 46). The earliest descriptions of HD were discussed in Chapter 46 as were theories concerning the etiologic

Lymph nodes involved by Hodgkin's disease show either partial<sup>148</sup> or total obliteration of normal follicular and sinusoidal architecture by a diffuse and frequently mixed infiltration of lymphocytes, histiocytes, eosinophils, plasma cells, and neutrophils. Accompanying Reed-Sternberg cells may be either sparse or plentiful. Histologic subclassification of Hodgkin's disease relies principally on differences in the cellular composition of this infiltrate, particularly on variations in the proportions of lymphocytes and histiocytes that it contains. Both the Rye classification<sup>133</sup> (see below) and the prior Jackson and Parker<sup>70</sup> scheme acknowledge that when the nodal infiltrate is comprised predominantly of mature lymphocytes the

disease is usually localized at discovery and the prognosis is relatively favorable. In this *lymphocyte-predominant* form of Hodgkin's disease (Fig. 50-1) (Jackson and Parker: paragramuloma), Reed-Sternberg cells, eosinophils, and histiocytes are sparse so that the disease may be mistaken for diffuse lymphocytic lymphoma by the casual observer. Alternately one may find Hodgkin's infiltrate comprised principally of histiocytes and very few lymphocytes. Eosinophils and Reed-Sternberg cells occur in varying numbers in this *lymphocyte-depleted* form of Hodgkin's disease (Fig. 50-2) but are usually more common than in the lymphocyte-predominant form. A varying amount of nodal fibrosis is also seen, usually distributed in random or

Fig. 50-1 Lymphocyte predominant Hodgkin's disease. The predominant cell is the small lymphocyte. Eosinophils and histiocytes are sparse and fibrosis is uncommon. Several Reed-Sternberg cells are seen in the upper left corner. Lymph node. H & E 200X. (Courtesy of Dr. R. W. McDivitt.)

Fig 50.2 Lymphocyte-depleted Hodgkin's disease. The predominant cell is the histiocyte. Lymphocytes are sparse. A few scattered eosinophils are seen but usually fewer than in the mixed cellular and nodular sclerosing types. Lymph node. H & E 400X. (Courtesy of Dr R. W. McOwitt.)

linear fashion. Lymphocyte-depleted Hodgkin's disease (Jackson and Parker Hodgkin's sarcoma) is usually a disease of older individuals, is more frequently generalized (stage III or IV, Table 50-1) at discovery than is the lymphocyte-predominant form, and has the least favorable prognosis of all the histologic types. The lymphocyte-depleted and the lymphocyte-predominant variants of Hodgkin's disease are the least common of the four histologic types<sup>23</sup> (page 1539).

Most commonly, Hodgkin's infiltrate is of a mixed type and includes numerous eosinophils, neutrophils, plasma cells, and rather evenly balanced numbers of lymphocytes and histiocytes. Reed-Sternberg cells are usually plentiful. Jackson and Parker referred to this variety as Hodgkin's granu-

loma.<sup>70</sup> It comprised 80 to 90% of cases, and these varied considerably in clinical course and prognosis. Some criticism of the Jackson-Parker classification has been obviated by the more recent Rye classification,<sup>133</sup> which follows the suggestion of Lukes, Butler, and Hicks and divides the mixed group according to whether or not the infiltrate is nodular or diffuse in distribution.<sup>104,105</sup>

In *nodular sclerosing Hodgkin's disease* (Fig. 50-3), microscopic nodularity is produced by interlacing bands of collagen which divide the more cellular portions of the infiltrate into discrete islands. In addition to nodularity, this type of Hodgkin's disease is distinguished by Reed-Sternberg cells that differ somewhat from the ordinary variety. These cells, referred to as *lacunar Reed-Sternberg*

**Table 50-1. Clinical Staging Classification for Hodgkin's Disease (Rye Conference, 1965)\*†**

<i>Stage I</i>	Disease limited to one anatomic region or to two contiguous anatomic regions on the same side of the diaphragm
<i>Stage II</i>	Disease in more than two anatomic regions or in two noncontiguous regions on the same side of the diaphragm
<i>Stage III</i>	Disease on both sides of the diaphragm, but not extending beyond the involvement of lymph nodes spleen and/or Waldeyer's ring
<i>Stage IV</i>	Involvement of the bone marrow lung parenchyma pleura liver bone, skin, kidneys gastrointestinal tract, or any tissue or organ in addition to lymph nodes spleen, or Waldeyer's ring

All stages subclassified as 'A' or 'B' to indicate the absence or presence respectively of systemic symptoms. The following documented symptoms, otherwise unexplained are significant: (a) fever (b) night sweats and (c) pruritus. Hodgkin's disease limited to non lymphoid organs is excluded from the classification. Waldeyer's ring consists of tonsils adenoids and related lymphoid tissue of the oropharynx.

\*From Tubiana et al.<sup>155</sup> courtesy of the authors and Cancer Research.

†Now replaced by Ann Arbor Classification Table 50-2.

cells, have very faint cytoplasmic staining and are separated from adjacent cells by an empty space or lacuna, most probably as a result of fixational contraction. Nodular sclerosing Hodgkin's disease is most frequently a disease of young adults, usually localized (stage I or II) at discovery, favorable in prognosis, and most often found in the cervical regions and mediastinum.<sup>42</sup>

Hodgkin's disease of diffuse mixed pattern is referred to as *mixed cellular* Hodgkin's disease (Fig. 50-4). In this form, fibrosis is fairly common and focal necrosis is observed in as many as 25% of patients.<sup>158a</sup> Like the lymphocyte-depleted variety, it has a propensity to be generalized at discovery, and carries a less favorable overall prognosis than does either the nodular sclerosing or lymphocyte-predominant type. Nodular scler-

osing and mixed cellular Hodgkin's disease each account for about 40% of cases at diagnosis.<sup>22a</sup>

*One must not assume from the preceding outline that histologic classification of Hodgkin's disease is always precise.* Most series report somewhere between 5 and 10% of cases that seem to defy such classification; and variation occurs among pathologists in classifying the remainder.<sup>22a,42</sup> Certainly, the parameters defining the boundaries between mixed cellularity, lymphocyte-depleted, and lymphocyte-predominant types provide considerable latitude for variation, as do differences of opinion concerning whether or not disease of diffuse mixed cellularity, with lacunar cells but without obvious fibrosis or nodularity, should be included in the nodular sclerosing group.<sup>81,149</sup> Evidence also suggests that when repeated biopsies are obtained throughout the course of the disease, the histologic classification may not remain constant. Whereas nodular sclerosis seems most persistent, only about 10% of this type shifting to a different histologic type on repeated biopsy, approximately 60% of other types may be expected to show variability in histologic classification if more than one biopsy specimen is obtained.<sup>249</sup> These factors must be considered in evaluating the overall significance of histologic classification.

Thus the classification most generally adopted at the present time<sup>131</sup> recognizes a rather distinctive form of Hodgkin's disease, nodular sclerosis, and a continuum of pathologic appearance that can be divided into lymphocyte-predominant, mixed cellularity, and lymphocyte-depleted stages (Fig. 50-5). It has been suggested that a cellular phase may precede the formation of collagen bands.<sup>81</sup> Nodes with the lacunar type of Reed-Sternberg cell may represent an early stage of nodular sclerosis.<sup>131,149</sup> In nodular sclerosing Hodgkin's disease, areas of necrosis may be observed, as may large, foamy macrophages.<sup>158a</sup> It should also be noted that although the Reed-Sternberg cell is so characteristic of Hodgkin's disease, it probably is not a neoplastic cell itself, since DNA synthesis is not observed in such cells.<sup>129</sup>

Fig 50-3. Nodular sclerosing Hodgkin's disease. Broad bands of collagen separate cellular nodules of tumor. Numerous lacunar Reed-Sternberg cells are intermixed with lymphocytes, histiocytes, plasma cells, and eosinophils. Lymph node. H & E 160X. (Courtesy of Dr R. W. McDivitt.)

**FREQUENCY OF VARIOUS TYPES.** Since diagnostic criteria are not exact, some variation in the frequency of various types as classified by different pathologists is to be anticipated. In one series of 302 patients, 31% of the cases were classed as nodular sclerosis, 27% as lymphocytic predominance, 32% as mixed cellularity, and 10% as lymphocyte depleted.<sup>154</sup> In another series of 252 patients the percentages were 45, 14, 21, and 19, respectively.<sup>112</sup> In still another referral center, nodular sclerosis was considered to be present in the majority of patients.<sup>81,86</sup> Some of the variation in percentage of histologic type from one to another series may be explained by different criteria for selecting patients for admission to an institution. However, as mentioned above, there is a considerable de-

gree of disagreement as to histologic type between different pathologists.<sup>33</sup>

The prognostic significance of the histopathologic classification and its relation to clinical staging are discussed on page 1553.

### Clinical Staging

Beginning with Trousseau in 1865, clinicians have proposed various clinical classifications of HD.<sup>122</sup> In order to provide some uniformity in reporting, a group of investigators agreed to utilize a single classification on a trial basis at the Rye (New York) Conference<sup>155</sup> (Table 50-1). In this classification, stages I through III represented increasing numbers of involved lymph node groups and IV represented extranodal spread of disease.

Fig 50-4 Mixed cellular Hodgkin's disease containing numerous lacunar histiocytes. Some observers include tumors of this histology in the nodular sclerosing category, even though neither nodularity nor sclerosis is obvious. Lymph node. H & E 400X. (Courtesy of Dr. R. W. McDivitt.)

Addition of A or B to each respective Roman numeral indicated absence (A) or presence (B) of fever, night sweats, or pruritus.

The classification of HD has continued to change as knowledge concerning which lesions are and which are not amenable to cure by radiotherapy has evolved. The most recently agreed upon classification<sup>26</sup> (Table 50-2) incorporates an important observation made since the Rye classification was recommended in 1965; namely, if extra-lymphatic disease is localized and related to adjacent lymph node disease it has approximately the same prognosis as that of disease which has not spread beyond that node. The disease-free

interval after therapy for stages II and III with or without local extension to adjacent non-lymphatic tissue has been found to be about the same.<sup>112</sup> Consequently, localized parenchymal lung involvement adjacent to an involved hilar node is no longer considered stage IV disease. Such local extension to pleura, bone, skin, or other soft parts also may be observed.<sup>24</sup> Procedures used to establish the stage should be incorporated into the staging classification (Table 50-3). Other changes from the Rye classification include a change in stage I-II designations and a change in symptoms that are considered to be of prognostic significance. Disease limited

to two contiguous node groups is now stage II rather than stage I, since survival with two groups on one side of the diaphragm more closely approximates survival when three groups are present than when only one is found.<sup>156</sup> Pruritus has been dropped as a significant symptom and weight loss has been added, to agree with recent findings regarding the significance of these manifestations.<sup>156</sup>

Examples of how such a classification is applied are given in Table 50-3. Additional changes in staging classification may be anticipated as knowledge of response to therapy as related to other abnormalities, such as degree of immunologic impairment, is acquired. Furthermore, the exact location of nodes may prove important in staging. Among 101 patients having high cervical nodes (submental, submaxillary, and jugular) as the presenting manifestation, involved supraclavicular and axillary nodes frequently were present, but in all these patients the medi-

astinum was spared.<sup>154</sup> In contrast, when the primary site (as defined by largest node size) appeared to be the lower cervical or supraclavicular region, the majority of the patients gave evidence of mediastinal disease.

## Presenting Features

### Symptoms

An enlarged painless cervical node (or nodes) without systemic symptoms is the most common presenting manifestation.<sup>70</sup> A history of fluctuation in size of the enlarged nodes is obtained frequently, as is spontaneous remission and exacerbation of other symptoms.<sup>78</sup> Fever, without other symptoms of infection, is relatively common, as are drenching night sweats, but chills are uncommon. *Periodic, regularly recurring* bouts of fever as described by Murchison,<sup>111</sup> Pel,<sup>121</sup> and Ebstein<sup>11</sup> may be experienced occasionally. However, virtually any type of fever

Fig. 50-5 Histologic classification of Hodgkin's disease (Rye conference<sup>123</sup> modification of Lukes and Butler's classification).<sup>101</sup> Lymphocyte predominance, mixed cellularity, and lymphocyte-depleted varieties represent a continuum of disease (indicated by the overlapping circles), while nodular sclerosis is a distinct variety of disease (See text for histologic descriptions.)

JALPUR [Raj]

**Table 50-2. Current Recommended Clinical Staging for Hodgkin's Disease ("Ann Arbor" Classification)\***

<b>Stage I</b>	Involvement of a single lymph node region or of a single extralymphatic organ or site
<b>Stage II</b>	Involvement of two or more lymph node regions on the same side of the diaphragm or localized involvement of an extra-lymphatic organ or site and of one or more lymph node regions on the same side of the diaphragm. Optionally the number of node regions involved is indicated by a subscript
<b>Stage III</b>	Involvement of lymph node regions on both sides of the diaphragm. This may or may not be accompanied by localized involvement of an extra lymphatic organ or site or involvement of the spleen or both
<b>Stage IV</b>	Diffuse or disseminated involvement of one or more extra lymphatic organs or tissues with or without associated lymph node enlargement. The reason for classifying a patient as stage IV is indicated by defining the site or sites by symbols. Extra lymphatic organs are defined as those other than lymph nodes, spleen, thymus, Waldeyer's ring, appendix, and Peyer's patches. Liver or bone marrow involvement always indicates Stage IV disease

**A-B Subclassification.** A refers to patients without B with defined general symptoms as follows:

Unexplained fever with oral temperatures above 38° C

Night sweats

Unexplained weight loss of more than 10% of body weight in the six months before admission

Unexplained pruritus no longer justifies B classification nor do other symptoms such as alcohol-induced pain

It is suggested that each patient be given a clinical designation based on the history, physical and radiologic examinations including isotopic scans and liver function tests as well as a histologic designation based on all biopsy material obtained subsequent to the initial diagnostic biopsy (Table 50-3)

\*From Carbone et al.<sup>74</sup> courtesy of the authors and Cancer Research

**Table 50-3. Examples of Staging Classification of Hodgkin's Disease**

**CS I-A PS I<sub>S-H-N-</sub>**

**Interpretation:** CS I-A (clinical stage I-A), PS I (pathologic stage<sup>75</sup> I), S— (splenectomy done and negative), H— (negative biopsy of liver), N— (additional lymph nodes negative), and M— (marrow biopsy negative).

**CS II-A PS III<sub>S-H-N-M-</sub>**

**Interpretation:** Clinical stage II-A but Hodgkin's involving spleen and abdominal nodes found at laparotomy, therefore, pathologic stage III-A, liver and marrow biopsies negative

**CS III-B PS IV<sub>H+</sub>**

**Interpretation:** Clinical stage III-B. Pathologic staging procedures terminated when liver biopsy was positive

\*Based on histologic examination of tissues removed at laparotomy

pattern from continuous low-grade to hectic daily swings may be observed.<sup>14,100</sup> Fever due to infection is uncommon until terminal stages of the disease are reached.<sup>14,100</sup> Weight loss may occur. Generalized pruritus without a rash is sometimes a very troublesome symptom. A peculiar and unexplained symptom is the development of pain very shortly after drinking small amounts of alcohol.<sup>31,73</sup> This type of pain may be elicited in as many as 17% of patients if alcohol tolerance tests are done,<sup>127</sup> but is less common as a spontaneous complaint.<sup>86</sup> The pain usually is at a site of HD infiltration and is transient, but may be severe. This symptom is reported in association with other conditions only rarely, but has been described by patients with eosinophilic granuloma of bone,<sup>99</sup> osteomyelitis, fractures, or carcinoma.<sup>73</sup> Other types of pain are infrequent unless bone is invaded or nodes compress nerves or nerve roots; the compression of nerves or nerve roots most commonly occurs in the retroperitoneal space. Complaints relating to extranodal disease such as cough from pulmonary infiltration, jaundice from hepatic invasion, or ab-

**Table 50-4. Frequency of Involvement of Various Lymphoid Structures in 340 Patients with Hodgkin's Disease\***

Site	Frequency	Percentage of Patients with Specified Area as Only Involved Site
Left cervical and/or supraclavicular nodes	71%	43%
Right cervical and/or supraclavicular nodes	59%	22%
Mediastinal nodes	62%	9%
Hilar nodes	11%	0
Left axillary nodes	26%	5%
Right axillary nodes	23%	9%
Para-aortic nodes	34%	2%
Iliac, inguinal, and/or femoral nodes	16%	9%
Spleen	13%	0

\*Adapted from Kaplan.<sup>85</sup>

dominal pain from disease of bowel or of thyroid enlargement are unusual, particularly as the only complaint. Initial symptoms of disease apparently limited to extranodal tissue<sup>89,137,146</sup> are much rarer in HD than in the non-Hodgkin lymphomas (Chapter 51).

### Physical Examination

Enlarged cervical or supraclavicular lymph nodes, especially those of the left side, are the most common physical abnormalities (Tables 50-4 and 50-5) (Fig. 50-6). Mediastinal disease (Fig. 50-7) is next most common, but usually is associated with supraclavicular disease; it is not a common site of localized disease (Table 50-4) nor is it often the largest area of involvement (Table 50-5). The majority of patients with supraclavicular-mediastinal disease have the nodular sclerosing variety of HD.<sup>85</sup> Enlargement of axillary or inguinal nodes without cervical adenopathy is less common than the converse. Generalized lymphadenopathy is present in a minority of patients. The nodes usually are not tender and changes in the overlying skin are unusual. When tenderness and skin changes are present they are thought to reflect rapid growth with stretching of nodal capsules. The nodes feel firm, but are not hard and are somewhat "rubbery," but, when extensive sclerosis or fibrosis is present, as in some patients with the nodular sclerosing or

lymphocyte depleted varieties, the nodes may be quite hard. In most patients the nodes are discrete and freely movable. Calcification may occur in nodes after they have been irradiated.<sup>167</sup>

*Splenomegaly* is present in a minority of patients and *hepatomegaly* is even less common. Palpable enlargement of the spleen has proved to be due to HD involvement of the spleen in only a third to one half the subjects.<sup>40,86</sup> Hodgkin's disease limited to the spleen is quite rare,<sup>85,154</sup> but we have seen such a patient; this patient had severe fever and weight loss at the time of death and the only disease found at autopsy was HD diffusely involving an enlarged spleen.

As discussed in Chapter 54, virtually any organ can be invaded by HD. However, evidence for disease in areas other than lymph

**Table 50-5. Apparent Site of Onset of Hodgkin's Disease as Judged by the Largest Area of Involvement at the Time of Diagnosis (348 Patients)\***

High cervical nodes	29%
Supraclavicular nodes	41%
Mediastinal structures	11%
Axillary nodes	4%
Abdominal nodes	13%
Spleen	1%

\*Adapted from data of Teillet et al.<sup>154</sup>

Fig 50-6 Enlargement of glands in the posterior triangle of the right side of the neck in a patient with Hodgkin's disease

nodes and spleen is present only in a small minority of patients at the time of diagnosis (page 1552). Abnormal physical or roentgenographic findings at diagnosis disclosed HD of lung in 11%, of the liver in 6%, of bone in 6%, and of pleura, skin, or other soft tissue in 2% or fewer in one series of patients.<sup>112</sup> As the disease advances the lung and liver become involved in many patients as do kidneys, stomach, and bowel in a lesser number (see Chapter 54).

#### Pattern of Spread

The apparent pattern of spread of HD is consistent with a unicentric origin in most patients, although multicentric origin in some patients cannot be ruled out.<sup>80</sup> When first consulting a physician, approximately 90% of the patients have disease in which contiguous spread via lymphatic channels could have occurred, at least if retrograde thoracic duct extension from supraclavicular to para-aortic nodes takes place. Retrograde lymphatic spread from involved nodes is thought to be the mechanism of spread to the skin.<sup>36</sup> Splenic disease may represent spread from para-aortic nodes, and hepatic disease probably results from hematogenous spread from the spleen.<sup>81</sup> Alternatively, spread to the spleen may be hematogenous and involved abdominal nodes may represent spread from the spleen.<sup>5</sup> Parenchymal lung involvement appears to be the consequence of direct invasion from involved hilar nodes or mediastinum.

Hematogenous spread to marrow or liver may be predicted to some degree if vascular invasion by HD can be demonstrated in nodes and spleen.<sup>130</sup> However, vascular invasion is not necessary for hematogenous spread to occur. The demonstration of Reed-Sternberg cells in thoracic duct drainage in all of seven patients found to have high para-aortic node involvement<sup>46</sup> suggests that cells from nodes involved with HD are regularly delivered to the blood of some patients. There is some evidence that the pattern of spread differs according to the histologic type of HD.<sup>67</sup>

#### Hodgkin's Disease In Children

HD in children is somewhat uncommon, but is quite similar to the disease observed in adults.<sup>47,74,125,130a,147</sup> The course in children may be more rapid than in adults if extensive disease is present at the time of diagnosis,<sup>47</sup> but, in general, response to therapy and survival are similar to those expected in adults.<sup>47,74,125,140a,171</sup> HD is exceedingly uncommon in children younger than age three, but has been reported in an infant of five months who also had thymic aplasia.<sup>160</sup> Strum and Rappaport<sup>147</sup> reviewed five other reports of HD in infancy and found none of them convincing. There is a marked male predominance in children and the pathologic classification is usually either nodular sclerosis or lymphocyte predominance.<sup>147</sup>

### Laboratory Findings

Anemia is present in no more than 50% of the patients at the time of diagnosis (Table 50-6).<sup>97</sup> Coombs' positive hemolytic anemia can be found when the diagnosis is made,<sup>16</sup> but is more common during the terminal stages of the disease<sup>45</sup> (Chapter 54). In most patients the anemia is mild, normochromic, and normocytic and is accompanied by a normal or reduced percentage of reticulocytes. Hypoferremia may be present, but, unlike anemias associated with many forms of chronic disease (Chapter 18), this is not necessarily accompanied by decreased transferrin levels.<sup>72</sup> Erythrocytosis was reported in one patient with HD.<sup>20</sup>

The leukocyte count may be increased<sup>97</sup>; leukopenia is unusual (Table 50-6). Leukocytosis most often reflects neutrophilia. Eosinophilia is more frequently written about than observed. However, extreme degrees of eosinophilia may be present.<sup>8,107,141</sup> Modest elevation of the leukocyte alkaline phosphatase usually is found during periods of active disease. Monocytosis may accompany the neutrophilia<sup>22</sup> and an increase in basophilic leukocytes is observed occasionally. Lymphopenia is present in one third<sup>36</sup> or more of HD patients (Table 50-6) and has long been recognized as a frequent finding.<sup>22</sup> The percentages of large and medium-sized lymphocytes and of lymphocytes synthesizing DNA are increased during active phases of HD and plasma cells may be observed in the blood.<sup>36</sup> Lymphocytes with nucleoli are found with greater than normal frequency.<sup>127</sup> The output of small lymphocytes from the thoracic duct decreases in lymphopenic patients.<sup>46</sup> Abnormal-appearing cells may be found on blood smears or if leukocytes are concentrated.<sup>15,58</sup> Some of these are quite nonspecific and may be found in patients with viral diseases or even in normal persons.<sup>58</sup> In that category are abnormally large monocytes with large vacuoles and large lymphocytes with deeply basophilic cytoplasm.

Reed-Sternberg cells may be observed in the blood; when leukocyte concentrates were examined they were found in 12%<sup>58</sup> to 19%<sup>15</sup>

\*Based on values published by Kaplan <sup>24</sup>

cell, possibly a precursor of the Reed-Sternberg cell, is even more often present in the blood.<sup>58</sup> This cell, as large as 40  $\mu$ m in diameter, has a nucleus that is oval or lobulated with fine, reticular chromatin and one or more large nucleoli and moderately basophilic cytoplasm. The presence of this cell or of Reed-Sternberg cells in the blood has been considered to be indicative of HD in the spleen.<sup>58</sup>

Although anemia, neutrophilia, and lymphopenia are less common with stage I disease than with other stages, they do not necessarily reflect the extent of disease (Table 50-6).

*Platelet counts* usually give normal values<sup>97</sup> although the count may be above normal and large bizarre platelets may be seen occasionally.<sup>22</sup> The finding of thrombocytopenia suggests bone marrow involvement. Pancytopenia is rare and usually reflects marrow involvement.

The *bone marrow* often is normal when examined by aspiration and biopsy. An increased myeloid:erythroid ratio may be observed, reflecting increased neutrophil production,<sup>7</sup> decreased erythrocyte production, or both. Marrow biopsy discloses HD (Plate III) in approximately 5% of patients at the time that the diagnosis is made.<sup>135</sup> HD in marrow may not be predictable from changes in the blood; in one study three of 11 patients

with marrow involvement were not anemic.<sup>50</sup> In other patients, some degree of fibrosis may be observed or nonspecific granulomas may be found.<sup>61,131,135</sup> The pathologic significance of these findings and the frequency with which HD in bone marrow is missed because of random sampling are questions that must await long-term follow-up of large numbers of such patients.<sup>131,135</sup> Reed-Sternberg cells may be recognized in smears made from aspirates,<sup>61,168</sup> but biopsy study is preferable for their demonstration.<sup>61,131</sup> Hodgkin's disease on rare occasions may appear to be limited to the bone marrow even after careful autopsy examination.<sup>163</sup> One of our patients, in whom this diagnosis was made ante mortem, complained of radiating abdominal pain, increasing weakness, and loss of weight and was found to have fever of the Pel-Ebstein type. There was marked pallor and slight hepatic enlargement as well as abdominal distention, but there was no adenopathy or splenomegaly and no masses or glands could be demonstrated in the abdomen; however, bone lesions were present (Fig. 50-8). The blood counts suggested aplastic anemia (Hb, 5 g/dl; WBC,  $1.2 \times 10^9/l$ ; platelets,  $88 \times 10^9/l$ ), but a moderate increase in percentage of reticulocytes (4.9%), together with the presence of nucleated red cells and occasional polychromatophilic corpuscles in the blood smears,

Fig 50-8. Two small areas of decreased density in the bones of the skull resembling metastases due to carcinoma, in a patient with 'bone marrow' Hodgkin's disease. The patient had severe anemia, leukopenia, and thrombocytopenia without glandular enlargement or splenomegaly. The only other bone lesion was increased osteoporosis of the bones in the region of the left wrist.

indicated the myelophthisic character of the anemia.

*Sedimentation rate and serum protein electrophoresis* often are abnormal and, while not of great diagnostic aid, may prove useful in judging whether disease activity is or is not present.<sup>13</sup> Albumin may be decreased and gamma globulin levels are often elevated in a diffuse pattern. Alpha-2 globulin levels often are quite high and may be so peaked as to mimic a para-protein spike (Fig. 50-9). Alpha-1 globulin usually increases in the presence of fever. Other tests that are likely to give abnormal results in patients with active disease and that to some extent tend to mirror the degree of disease activity are C-reactive protein,<sup>165</sup> hydroxyproline levels in plasma,<sup>95</sup> serum complement, serum copper and zinc, leukocyte alkaline phosphatase, haptoglobin, serum protein-bound hexose, and hexosamine and bradykinin tests.<sup>86</sup> The serum copper level appears to be a very sensitive index of the presence of disease.<sup>154a</sup> However, there is little evidence that any of these tests are more specific than the erythrocyte sedimentation test (ESR). On the other hand, if tumor-associated antigens are

shown to be present in most patients with active disease,<sup>30a</sup> this test should become the best means of determining whether or not there is active disease.

*Uric acid* excretion may be increased, but hyperuricemia is uncommon except during rapid tissue destruction by therapy. Even then, hyperuricemia of a degree that would

Fig. 50-9. Serum protein electrophoretic pattern from a patient with untreated, stage II-B Hodgkin's disease. Immunoelectrophoresis indicated that the alpha 2 elevation was not due to a paraprotein; note the diffuse elevation of gamma globulin.

produce renal impairment (Chapter 54) is unusual. Consequently, therapy for hyperuricemia rarely is indicated. *Hypercalcemia* is uncommon and usually reflects disease of bone (Chapter 54) although roentgenographic evidence of bone disease may be absent.<sup>79</sup> Serum *alkaline phosphatase* may be increased as a result of liver disease and less frequently because of bone disease.<sup>4</sup> This increase, even when identified as the liver isozyme, is not diagnostic of hepatic parenchymal HD, but when such disease is present the value almost always is elevated.<sup>4</sup>

**IMMUNE SYSTEM.** *Hypogammaglobulinemia* and reduced ability to form circulating antibodies are unusual<sup>12,13</sup> and when they are found, widespread severe disease almost always is present. We have encountered these changes at the time of diagnosis only in one patient (Fig. 50-15).

**Anergy** as reflected by loss of previously existing skin hypersensitivity to agents such as old tuberculin, mumps, trichophyton, histoplasma, and varidase, or inability to acquire such sensitivity as tested with dinitrochlorobenzene is a common finding.<sup>2,139</sup> (Chapter 46) In the presence of anergy, lymphocyte conversion with phytohemagglutinin<sup>60,119</sup> often is abnormal. The presence of anergy interrelates to some degree with the clinical stage of disease, the pathologic classification, and the level of circulating lymphocytes.<sup>2,60</sup> Anergy is more often associated with stage III or IV disease than with stage I or II. It is more commonly found in the lymphocyte-depleted variety of HD than when there is lymphocyte predominance and is more likely to be found when there is lymphocytopenia than when blood lymphocytes are present in normal concentrations.<sup>2</sup> Whether anergy is present because of extensive disease or whether extensive spread of HD has occurred because of anergy are important, but unresolved, questions. Deficiency of pyridoxal phosphate often is demonstrable in patients with active HD and has been suggested as a possible cause of anergy.<sup>28</sup>

When a therapeutically induced remission has continued for some time the above meas-

ures of cellular immunity often return to normal.<sup>28,60</sup>

## Staging Procedures

The therapeutic approach to the patient with HD (page 1556) is governed by the extent of disease at the time of diagnosis. Recognition of the fact that most patients with sharply localized HD can be cured by radiotherapy has led to continuing refinement of means for determining the extent of disease. However, the number of staging procedures that are carried out should be geared to the intended means of treatment. For instance, if it is the practice of the physician to give "total nodal" irradiation (page 1557) to all patients except those with stage IV disease, then only those procedures designed to detect stage IV disease should be employed. Conversely, if more limited radiotherapy is planned for limited disease, more extensive staging is required.

Once a pathologic diagnosis of HD has been established, additional studies in logical sequence are indicated. Detailed guidelines have been published.<sup>136</sup> The history should be reviewed with particular attention to the presence or absence and severity and duration of fever, night sweats, and weight loss as well as pruritus, alcohol-induced pain, and whether or not hydantoin-type drugs have been taken by the patient, since these may be associated with the development of lymphadenopathy (page 1553). All commonly involved lymph node areas should be carefully palpated and uncommonly involved sites such as epitrochlear, parascapular, and popliteal areas should also be examined. The size of the spleen and of the liver should be determined, the skin should be examined for suspicious lesions, and the skeleton should be palpated in search of areas of bone tenderness.

An x ray of the chest should be obtained and, if any suspicious areas are present, tomograms should be done. A bone marrow biopsy should be carried out. The marrow is involved in few patients with HD (page 1546), but, since the procedure is simple and since

positive results indicate stage IV disease, this procedure is advisable early in the work-up.

Liver function tests should be performed; the serum alkaline phosphatase level, especially, should be determined. Certain liver function tests, such as the BSP, have no apparent value in predicting the presence or absence of HD of the liver.<sup>40</sup> If the liver is enlarged or if it is of normal size but the function tests give markedly abnormal findings, isotopic scan of the liver and spleen may be advisable.<sup>108a</sup> If these studies suggest involvement of the liver, needle biopsy may be helpful. Multiple biopsies during abdominal exploration more often give positive findings than does single closed needle biopsy, but if the latter yields positive indications of HD, laparotomy becomes unnecessary as this alone justifies stage IV classification. An alternative to closed needle biopsy or exploratory laparotomy is peritoneoscopy, thereby obtaining a liver biopsy specimen under direct vision. In 38 selected patients, six were found to have HD of the liver by this procedure, a figure comparable to that obtained in similar patients subjected to laparotomy.<sup>41</sup> Of 21 of those patients in whom closed liver biopsies showed no abnormality, positive findings were obtained on peritoneoscopy in two.

Roentgenograms of vertebrae, pelvic, and proximal long bones as well as special films of any area of bony tenderness should be obtained. The laboratory procedures described above, in addition to examination of the blood for anemia, assessment of leukocytes and platelets, determination of ESR, blood urea nitrogen, serum uric acid, and blood glucose, and serum protein electrophoresis, as well as urinalysis, should be carried out in all patients, irrespective of their clinical staging classification as judged by physical examination. Additional studies will depend upon the extent of disease apparent at this point in the work-up and upon therapeutic intentions.

If "total nodal" irradiation (page 1557) is to be used for stages I, II, and III, then the only real consideration is to rule out the

possibility of stage IV. If the bone marrow, skeletal, lung, liver (including biopsy), and skin examinations do not show involvement, then the evaluation has been completed. If radiotherapy is to be limited to one side of the diaphragm when HD appears to be so limited and/or if chemotherapy is to be used for stage III-B, then further evaluation is in order. The common situation is clear evidence of disease above the diaphragm, with no or questionable evidence of subdiaphragmatic disease (clinical stage I, II-A, or II-B). In this circumstance, questionably enlarged inguinal nodes can be studied by excisional biopsy. A bilateral, lower-extremity lymphangiogram also can be obtained.

*Lymphography*<sup>32</sup> is performed by identifying a lymphatic vessel through a small incision on the upper surface of each foot and injecting radiopaque dye into the vessel. The dye can be observed in inguinal, iliac, and para-aortic nodes within 24 hours. Nodes involved with HD often are larger than normal and have rounded, punched-out appearing filling defects giving them a "lacunar" or "foamy" pattern.<sup>159</sup> However, this appearance is also seen in other types of lymphoma, fungal diseases, and sarcoidosis, to name but a few conditions; consequently, it is in no sense diagnostic of HD.<sup>159</sup> It is noteworthy that pulmonary symptoms may be produced when the dye enters the pulmonary vasculature; the test is therefore contraindicated in patients with any significant form of pulmonary disease.

If multiple, enlarged retroperitoneal nodes with the characteristic foamy "lymphomatous" appearance are present, one may choose to make a presumptive diagnosis of stage III disease without histologic proof, particularly when the patient is symptomatic (III-B). However, since there is a possibility that nodes considered positive on lymphangiography may not reveal HD on pathologic study (page 1550),<sup>159</sup> an exploratory laparotomy may be advisable. Inferior vena-cavography is of some supplemental help in detecting retroperitoneal disease, but intravenous pyelography rarely gives added information.<sup>93</sup>

If the lymphangiogram gives negative or equivocal findings, exploratory laparotomy<sup>118a</sup> should be considered. At the time of laparotomy, all accessible abdominal node areas are observed and/or palpated, the spleen is removed, and a wedge biopsy and multiple needle biopsies of the liver are carried out. Lymphangiography may reveal enlarged nodes in the upper retroperitoneal chain, which is not easily accessible to the surgeon and may guide him to suspicious nodes. It is therefore advisable to undertake this procedure routinely before performing an abdominal exploration. It may be advisable to obtain a large section of marrow from the iliac crest during the exploratory procedure.<sup>13a</sup> At the same time, in the female the ovaries and fallopian tubes can be moved to a more lateral position so that the ovaries are spared direct irradiation when radiotherapy employing the "inverted Y" is to be given subsequently<sup>10</sup> (page 1557).

In summary, *laparotomy and splenectomy* may be considered if: (1) stage IV disease is not certain; or (2) the patient appears to be in stage I or II and radiotherapy will be limited to the "mantle" (page 1557) if the abdomen proves to be free of HD; or (3) the patient appears to be in stage II-B and chemotherapy will be given if the abdomen contains HD.

Other studies that may be of some aid include whole body gallium<sup>124,127</sup> and selenium<sup>65</sup> scintigrams and studies of delayed hypersensitivity.

#### Value of Lymphangiogram, Exploratory Laparotomy and Splenectomy

A lymphangiogram was reported to be abnormal in 0 to 36% of patients thought to have stage I disease and in 14 to 51% of patients thought to have stage II disease in whom no palpable disease was found below the diaphragm.<sup>18</sup> In patients with positive lymphangiographic findings, pathologically positive nodes have been demonstrated at laparotomy in approximately 70 to 90%<sup>40,86,128</sup> (Table 50-7). Considering the fact that positive nodes are undoubtedly missed in certain instances, this indicates an accuracy in excess of 80% for positive lymphography.<sup>134</sup> When the lymphangiogram gives negative or equivocal evidence, positive nodes have been found in 10 to 30% of patients subjected to laparotomy.<sup>128,134</sup> In most instances, positive nodes found at laparotomy in patients with negative lymphangiographic findings have been in areas not filled by bipedal lymphangiography. Usually these will be nodes in the hilar area of the spleen (Table 50-7), but less commonly nodes of the mesen-

Table 50-7. Results of Laparotomy in 100 Consecutive Untreated Patients with Hodgkin's Disease Examined at Stanford University\*

Site	Preoperative Assessment	Number of Patients	Percent of Patients in Whom Hodgkin's Disease Was Found at the Site	
			Para-aortic	Splenic Hilar
Abdominal nodes	Positive lymphangiogram	23	74	4
	Negative lymphangiogram	57	4	9
	Equivocal lymphangiogram	20	15	5
Spleen	Splenomegaly present	16		50
	Splenomegaly absent	84		24
Liver	Liver disease suspected	15		7
	Liver disease not suspected	85		2

\*Adapted from Table 4.6 of Kaplan.<sup>14</sup>

tery, celiac axis, or porta hepatis region will be infiltrated with HD. The last areas are involved only rarely; Kaplan<sup>86</sup> reported that only two of 340 patients had HD in mesenteric nodes. Thus, technically good lymphangiography gives reasonably accurate information, perhaps more accurate than surgical exploration of the retroperitoneal node chain. Small series suggesting a high degree of inaccuracy for lymphangiography<sup>18,158</sup> have been contradicted by subsequently published series which included much larger numbers of patients.<sup>63,86,134</sup> Nevertheless, every pattern of lymphoma may be simulated by a reactive process.<sup>22a,119a</sup>

Whether or not there is *splenic disease* is perhaps the most useful information obtained at laparotomy. This is determined by splenectomy and multiple-section examination. A palpably enlarged spleen is not necessarily enlarged because of HD, as mentioned earlier (page 1543). Conversely, HD may be found in grossly normal-appearing spleens in almost one fourth of the patients<sup>131</sup> (Table 50-7). If para-aortic nodes are involved, splenic involvement is likely. Of 21 patients with para-aortic lymph node invasion, 15 were found to have splenic involvement.<sup>128</sup> Liver involvement is unusual in the absence of

splenic disease.<sup>134</sup> In as many as 20% of patients with involved para-aortic lymph nodes or spleen, hepatic invasion was demonstrated.<sup>40</sup>

### Frequency of Various Clinical Stages

Careful staging reveals previously unsuspected areas of disease in a significant number of patients. Even so, it would appear that at least 50% of patients when first seen have stage I or II disease and fewer than one fourth are in stage IV.<sup>81,86,112,159</sup> Patients with lymphocyte predominance or nodular sclerosis are more likely to have stage I or II disease than are patients with mixed cellularity or lymphocyte depletion (Table 50-8). Using the Rye classification and following extensive staging procedures, among 340 consecutive patients Kaplan found 26% to be in stage I, 35% in II, 33% in III, and 6% in IV.<sup>85</sup> The frequency of stage B type of symptoms increases steadily as more extensive disease is found (Table 50-8).

## Diagnosis

Diagnosis of HD requires demonstration of the characteristic histologic picture (page

**Table 50-8. Interrelation of Histologic Classification and Clinical Staging at the Time of Diagnosis in 252 Patients with Hodgkin's disease.\* (Rye Classification)**

Histologic Type	Number of Patients	% of Patients with Clinical Stage				
		I	II	III	Local Extension from Node† IV	Diffuse IV
Lymphocyte predominance	35	14	49	32	3	3
Nodular sclerosis	114	5	50	21	12	12
Mixed cellularity	54	8	37	35	7	13
Lymphocyte depletion	49	6	43	20	6	25
Total	252	7	46	26	9	13

\* Adapted from Musshoff<sup>112</sup>

† Extension from a node, not stage IV in newest classification (Table 50-2)

1535). While there are certain clinical and laboratory features that allow one to suspect that a lymphoma rather than other causes of lymph node enlargement is present (Chapter 40), and features such as pruritus, alcohol-induced pain, lymphopenia, and neutrophilia suggest HD rather than another form of lymphoma (Chapter 51), histologic proof is necessary. Indications for lymph node biopsy and preferential sites for biopsy were discussed in Chapter 40. Two types of diagnostic problems are encountered with some frequency; namely, patients in whom the findings in the initial lymph node biopsy are not compatible with HD but who eventually develop the disease and patients who have symptoms compatible with HD, usually fever, but in whom no palpably enlarged lymph nodes are present and the chest film shows no abnormality.

**NONDIAGNOSTIC LYMPH NODE BIOPSIES.** Although the "typical" histologic characteristics of lymph nodes in the various forms of HD (page 1535) and non-Hodgkin's lymphoma (NHL) (Chapter 51) are recognized readily, there is no single absolute histologic criterion for the recognition of malignant lymphoma.<sup>37</sup> Initial lymph node biopsies from patients who eventually develop HD or NHL may reveal "reactive hyperplasia" and, even on retrospective review, no evidence clearly indicating malignant lymphoma may be found.<sup>37</sup> Failure to make the diagnosis may be due to the fact that one is dealing with the early stage of HD or with nodes adjacent to tumor that are reacting to the tumor. Sampling errors also are possible. Normal or enlarged but nondiagnostic nodes may be interspersed with nodes containing HD.<sup>145</sup> Multiple sections from a node must be examined before the node is considered to be nondiagnostic, since minute foci of HD may be present.<sup>148</sup> When a biopsy fails to reveal the typical histologic picture, the decision to remove another node or to observe the patient at frequent intervals must depend upon the clinical state of the patient and the degree of clinical suspicion of lymphoma (Chapter 40).

*Nonspecific granulomas* may be observed in lymph nodes, liver, spleen, and marrow of patients known to have HD.<sup>19,80,103</sup> In some patients, coexistent sarcoidosis has been considered<sup>35</sup> and, in fact, an increased frequency of sarcoidosis in association with HD has been suggested,<sup>19</sup> but, in other cases, no ancillary evidence to suggest sarcoidosis was found.<sup>19,80,103</sup> Usually it is probably best to assume that such granulomas are reactive rather than representing an early stage of HD invasion, but long-term follow-up will be required to determine if this assumption is correct.

*Reed-Sternberg cells*, while necessary to make a firm diagnosis of HD<sup>82</sup> (page 1535), are not specific for this condition. Cells resembling Reed-Sternberg cells have been observed in lymph node biopsy specimens from patients with infectious mononucleosis,<sup>106,108,150</sup> patients thought to have Burkitt's lymphoma,<sup>166</sup> following treatment of patients thought to have various types of NHL,<sup>149,150</sup> and from patients with carcinoma of the breast or lung, malignant melanoma, malignant fibroxanthoma, benign thymoma, multiple myeloma, or myositis.<sup>150</sup>

#### Patients without Palpable Disease

In some patients with HD, a mediastinal or hilar mass may be noted on routine x-ray examination of the chest or x-ray examination may be undertaken because of symptoms from such a mass. Other patients may consult the physician because of fever, fatigue, weight loss, pruritus, or other constitutional symptoms. In a minority of both types of patients no palpably enlarged nodes are available for biopsy. When there is mediastinal disease, obtaining a biopsy specimen by use of a mediastinoscope<sup>132</sup> is a much less traumatic experience for the patient than is thoracotomy. In patients who have symptoms suggestive of HD but no palpable nodes and whose chest x ray shows no abnormality, bipedal lymphangiography should be done. If this gives positive findings and/or if the spleen is palpable, diagnostic exploratory

laparotomy is advisable unless a closed needle biopsy of the liver establishes the diagnosis. If the liver biopsy and the lymphangiogram reveal no abnormality and if the spleen is not enlarged, HD is unlikely as a cause of the patient's symptoms (Chapter 40).

*Hydantoin derivatives* used as anticonvulsants may produce lymphadenopathy that cannot be distinguished histologically from HD or other forms of lymphoma.<sup>86</sup> In most circumstances, lymphadenopathy regressed when use of the drug was stopped, but in other patients the presence of true HD or NHL was established. Whether HD or NHL occurs with greater frequency in patients receiving anticonvulsants than in those not receiving such drugs is not entirely clear. If a biopsy has been compatible with a diagnosis of lymphoma in a patient in whom such medications have been employed, therapy for lymphoma should be delayed until it can be ascertained if discontinuing the use of the anticonvulsant leads to regression.

Other benign conditions that may lead to enlarged nodes with histologic changes similar to those of HD include lymphadenitis following smallpox vaccination,<sup>62</sup> herpes zoster, and toxoplasmosis.<sup>86</sup>

Hodgkin's disease beginning in the thymus is easily distinguished from primary *thymic tumors* such as the protoplasmic, small-cell, or spindle-cell type,<sup>84</sup> but there is some controversy whether *granulomatous thymoma* is or is not the same disease as nodular sclerosing HD of the thymus.<sup>50,87</sup> In some patients, later spread of disease histologically indistinguishable from HD to other parts of the body constitutes the best evidence that the disease is primary nodular sclerosing HD of the thymus.<sup>50,87,114a</sup>

## Prognostic Variables

The following factors have been well documented as having prognostic significance at the time of diagnosis: (1) clinical extent of disease—the less extensive the disease, the better the prognosis; (2) histologic type—lymphocyte predominance and nodular sclerosis imply a better prognosis than does

mixed cellularity which, in turn, is a more favorable histologic pattern than lymphocyte depletion; (3) sex—females live longer with HD than do males; (4) age—patients over 30 have a poorer prognosis than younger ones; and (5) systemic symptoms—patients with symptoms such as fever, night sweats, and weight loss have a poorer prognosis than those without these symptoms. All of these factors appear to be interrelated in part, but some are clearly independent prognostic variables.<sup>17,23,35,92,100,129,156</sup>

Lymphocyte predominance and nodular sclerosis primarily are associated with localized (stages I and II) disease, while lymphocyte depletion is associated with more widespread disease (Table 50-9). Thus, as anticipated from this association, prognosis for survival is best in patients with lymphocyte predominance and nodular sclerosis and worst in those with lymphocyte depletion (Table 50-9). However, there is some evidence that, even within clinical stages, histologic sub-type may have importance. For example, analysis of 377 patients showed that within stages, I, II, and III, patients with lymphocyte depletion tended to survive for a shorter time, whereas, within stage III<sup>105</sup> or IV,<sup>102</sup> patients with lymphocyte predomi-

**Table 50-9. Relationship of Histologic Classification to Clinical Classification and Survival\***

Histologic Type (1220 Patients)	Percent of Each Type† with Clinical Stage I or II	Percent of Each Type Surviving Five Years
Lymphocyte predominance, 13%	89%	66%
Nodular sclerosis, 40%	71%	56%
Mixed cellularity, 32%	48%	30%
Lymphocyte depleted, 16%	33%	16%

\*Based on seven series of patients reviewed by Butler.<sup>23</sup>

†Based on three of the seven series totaling 439 patients.

nance tended to survive longer than did those with other histologic types.<sup>102</sup> Mixed cellularity as well as lymphocyte depletion imply a poorer prognosis even if there is only stage I or stage II disease than does lymphocyte predominance or nodular sclerosis.<sup>88,105</sup>

Age and sex influences may not be independent variables.<sup>156</sup> The incidence of nodular sclerosing HD is higher in young than in old persons and in women than in men.<sup>113</sup> Whether the excess of nodular sclerosis fully explains the prognostic advantage of the young female requires further study.<sup>129</sup>

A "B" classification implies a poorer prognosis than "A" in any of the four numerical clinical stages. Weight loss and fever are the symptoms with the gravest prognostic significance; night sweats have some importance, but pruritus has no apparent prognostic implication.<sup>156</sup> The importance of symptoms is such that in stage III the decision to attempt curative radiotherapy is often based on the absence of symptoms. Why HD produces fever, weight loss, or pruritus is unknown.

Anemia, neutrophilia, and lymphopenia are correlated to some degree with stage of disease (Table 50-6); they may have no independent prognostic implications. The erythrocyte sedimentation rate (ESR) is not well correlated with extent of disease, but in patients without anemia or systemic symptoms an elevated ESR may indicate a relatively poor prognosis.<sup>156,162</sup>

The possible prognostic implications of such factors as anergy are still under study. Anergy usually is present in patients with advanced disease, but to date there is no evidence that it has any predictive value per se.<sup>34,170</sup> The anatomic site of lymph node disease may prove to be important (page 1541).

## Course of Disease

The course of HD depends upon the quality of response to therapy and the apparent degree of "malignancy" of the tumor, interrelated factors which can be predicted in part by the criteria just discussed.

## Duration of Survival

Median duration of survival, a figure often used in discussing the leukemias (Chapters 47 to 49), has little meaning in a disease such as HD in which a significant proportion of patients may be cured. However, in a series of 137 patients studied by us<sup>100</sup> before curative therapy was considered possible, median survival was more than 10 years in stage I, seven years in II-A, three years in II-B, and two years in stages III and IV (staging limited to physical examination and chest x ray in most cases). Survival probably is prolonged by "non-curative" radiotherapy and chemotherapy,<sup>3,129</sup> although this is somewhat difficult to prove<sup>118</sup> since there are no reports of survival in large series of untreated patients.<sup>100</sup> More than half of all patients with stage I or II disease should survive for more than five years if histologic study shows lymphocyte predominance or nodular sclerosis, but survival may be shorter if mixed cellularity or lymphocyte-depleted disease is present (Table 50-9).

## Definition of Cure<sup>33</sup>

Easson and Russell<sup>43</sup> found that, in patients who were treated by irradiation and who remained free of recurrence for a period of approximately 10 years after the diagnosis has been made, the death rate from all causes could not be distinguished from the death rate of the normal population. Thus, they suggested that cure could be defined in terms of disease-free interval following initial therapy. Further analysis seems to support the general validity of this as a general concept.<sup>33</sup> However, there is no known duration of relapse-free interval that affords a given patient a complete guarantee that disease will never recur.<sup>29,84</sup> Instead, as each relapse-free year accrues the probability of relapse in the coming year diminishes (Fig. 50-10). After five years of disease-free interval there is approximately a 1%/year possibility of relapse. These data were compiled from various institutions<sup>33</sup> on the basis of patients considered to have stage I or II disease who had

Fig 50-10. Probability of relapse in successive years following therapy with irradiation or four-drug combination chemotherapy (From data of combined irradiation series<sup>53</sup> and DeVita and Carbone's original series of patients treated with "MOPP"<sup>59</sup>)

been treated by radiotherapy. Admittedly, accuracy of staging may be questioned, particularly for the group with the longest follow-up. In certain small series of carefully staged and vigorously treated patients, such as those of Kaplan<sup>54</sup> and Musshoff,<sup>112</sup> relapse has not been observed in those at risk during the fifth through eighth disease-free years. A relapse rate curve similar to that following radiotherapy was noted in a small group of subjects treated with combination chemotherapy (Fig. 50-10). Although for the present, an exact definition of cure cannot be given, a disease-free interval of four to five years following therapy provides a reasonable statistical probability that a cure has been achieved.<sup>53,84</sup> By this definition, cure is anticipated in a significant percentage of patients treated by radical radiotherapy (page 1556) and it is possible, although not yet proven, that a number of patients with advanced disease may be cured by four-drug combination chemotherapy (page 1559).

#### Course in Patients Who Are Not Cured

Even when disease cannot be completely eradicated, repeated complete or partial remissions can be induced, even though even-

tually the disease cannot be controlled and death occurs. Pre-terminal, uncontrolled disease may not be characterized by formation of large, bulky tumors; often, in fact, it is characterized by minimal palpable lesions and yet there is considerable fever, weight loss, and consequent cachexia. Even at autopsy there may be no evident disease in nodes.<sup>69,91</sup> Formation of troublesome pleural or peritoneal serous effusions is not uncommon.<sup>161</sup> Jaundice is observed at some time during the course of disease in approximately 20% of patients and while it is most commonly accounted for by HD invasion of the liver, a diverse number of causes is possible which are difficult to distinguish from one another unless a biopsy specimen of the liver is obtained<sup>98</sup> (Chapter 54). A variety of peculiar and poorly understood complications such as *nephrotic syndrome*<sup>126</sup> may develop during the course of the disease (Chapter 54). Even with aggressive therapy, complete control of the disease is not achieved, even for a short time, in a few unfortunate patients; in many of these the histologic picture is that of lymphocyte depletion.<sup>112a</sup> Other patients appear to have an innately less aggressive disease. Patients have been described who lived for 26 and even 33 years but were never clearly in complete remission throughout the entire course of the disease.<sup>27</sup> As noted by the occasional relapses after many years free of disease following therapy (page 1554), HD may remain dormant for protracted periods; alternatively, perhaps such cases represent re-induction of disease rather than re-growth of the original tumor.

The cause of death is quite variable. Many patients die with increasing fever and cachexia in the absence of a single identifiable cause of death. Hepatic or pulmonary failure secondary to invasion by HD may lead to death (Chapter 54). Tuberculosis, toxoplasmosis, or severe systemic herpes virus infection<sup>25</sup> may develop as a result of anergy, or terminal pyogenic bacterial infection may occur in association with tumor invading the lung or following neutropenia and immune depression resulting from therapy (Chapter 54). Some degree of bone marrow failure,

reflected in pancytopenia or in the prompt appearance of pancytopenia following small amounts of therapy is fairly common late in the disease. This may be the result of HD and fibrosis in the marrow, unrepaired damage from irradiation and chemotherapy, or combinations of these events. A wide variety of complications such as multifocal leukoencephalopathy have been the cause of death (Chapter 54)

## Therapy

Cure of disease constitutes the proper goal of therapy in *all* previously untreated patients with HD and even in those who have relapsed following curative attempts with radiotherapy.

*Palliation* is presently the only practical goal in patients in whom relapse occurs after an attempt to cure the disease with radiotherapy followed by chemotherapy, or in those in whom chemotherapy was employed as the initial curative measure. Defining the goal as cure or palliation is a decision which must be made because attempts to cure with radical irradiation therapy or with four-drug combination chemotherapy are associated with sig-

nificant morbidity and even occasional mortality. Such morbidity induced by therapy must be kept to a minimum if only the goals of palliative therapy (Chapter 55) are to be attained.

Although on rare occasions cures have followed simple surgical excision, attempts to cure by radical node dissection have been unsuccessful<sup>1</sup> on the whole. Spontaneous remissions, however, have been reported.<sup>116</sup>

## Radical (Curative) Radiotherapy

Although it had long been known that a few patients were apparently cured following radiotherapy<sup>169</sup> or even chemotherapy<sup>100</sup> and some radiotherapists had advocated "sterilization" of lesions,<sup>54</sup> it was the studies of Peters<sup>123</sup> and Easson and Russell<sup>43</sup> that provided the first evidence that cure is a reasonable goal of radiotherapy. Kaplan<sup>92,93</sup> developed scientific guidelines for achieving this goal by studies in which it was shown that the likelihood of recurrence of disease at an irradiated site was less than 5% if 3500 rads or more were delivered to that site within a period of approximately four weeks (Fig. 50-11); recurrence was only about 2% if 4000 rads were given.<sup>96</sup> Delivery of this

Fig 50-11 Rate of recurrence of Hodgkin's disease in a given treatment field as a function of dose of irradiation delivered to that field (From Kaplan,<sup>92</sup> courtesy of the author and Cancer Research)

amount of irradiation in that short a time to a tumor requires the use of the therapy machines developed during the last two decades (see Chapter 55). "Conventional" 250-kilovoltage x-ray treatment machines produce intolerable skin damage that is largely avoided by the use of high-energy rays generated by megavoltage linear accelerator, telecobalt, or betatron apparatus.<sup>86</sup> However, kilovoltage therapy is still utilized and advocated by some.<sup>68</sup>

Thus, cure can be anticipated if 3500 to 4000 rads are delivered to *all* existing tumors within four weeks. The total dose may be more important than the delivery interval since a high cure rate has been reported if 4000 rads was delivered in six rather than three to four weeks.<sup>77</sup> The probability of cure in each treatment field appears to be an independent variable.<sup>86</sup> Thus, if the probability of cure of a single area is 98% with 4000 rads, the probability will decrease to 92% (.98<sup>3</sup>) if three areas are involved. Similarly the probability of cure of a single area with 3500 rads will decrease from 95% to 86% if three areas are involved. For this reason the total dose given to involved areas may be more critical when multiple sites are involved than when a single site is affected.

Irradiation of areas adjacent to and in the probable natural line of spread of disease from areas of known involvement has been advocated (*extended field irradiation*). It seems reasonable to suspect that inapparent spread has occurred to adjacent areas in some patients. Thus, most would agree that "mantle" therapy is indicated for stage I or II disease above the diaphragm and the "inverted Y" for stage I or II disease below the diaphragm (Fig. 50-12A and B). If the spleen has not been removed it should be irradiated in addition to the inverted Y. All areas are given 3500 to 4000 rads within four weeks, if possible. Following the same reasoning it has been argued that the para-aortic area (Fig. 50-12C), or even the entire lymph node chain (Fig. 50-12D), should be irradiated even in patients with stage I supradiaphragmatic disease.<sup>85</sup> However, it is generally agreed that, if stage III disease is present, "total nodal" irradiation (Fig. 50-12D) should be given. This term is a misnomer, however, in the sense that many peripherally located lymph nodes are not treated.

Although the reasoning behind extended field irradiation appears sound and reported results appear quite good in some instances, it must be emphasized that the case for its

Fig. 50-12. Treatment fields employed with extended field irradiation therapy, the mantle (A), the inverted Y (B), mantle and para-aortic (C), and "total nodal" (D). The spleen is irradiated in conjunction with the inverted Y unless it has been removed.

use has not been proved.<sup>17,92</sup> A randomized comparison of limited versus extended field therapy was stopped when it appeared that the additional irradiation resulted in a significantly longer disease-free interval. However, further analysis disclosed the fact that the two treatment groups had not been really comparable.<sup>86</sup> Nevertheless, a preliminary report of a randomized study of the mantle versus total nodal therapy in stages I and II disease suggests that total nodal therapy may be superior<sup>77</sup> (Fig. 50-13). Randomized study of the possible value of prophylactic irradiation is needed.<sup>115</sup> There is need also for continued randomized comparative studies based on increasing knowledge of the pattern of disease spread. For instance, were the case for total nodal irradiation for stages I and II disease proved desirable, is mediastinal irradiation

justified in a patient with high cervical stage I disease in view of the rarity of mediastinal disease in that circumstance?<sup>154</sup>

**Toxic effects** of irradiation with 3500 to 4000 rads are considerable. Organs such as the bone marrow, lung, heart, kidney, liver, and spinal cord may be damaged irreparably by this dose<sup>76</sup> (Chapter 55). Acute myeloblastic leukemia and CML probably have been induced in treated patients<sup>152</sup> (Chapter 46). Thus, continued comparison of series of patients treated by different regimens of radical irradiation must also include long-term comparisons of the causes and severity of morbidity and of mortality<sup>66</sup> as well as the frequency of relapse from HD. Death from irradiation-induced pulmonary fibrosis cannot be considered preferable to death from HD, and other complications (Chapter 55) such as radiation-induced pericarditis with subsequent constrictive fibropericardium<sup>112</sup> cannot be dismissed lightly.

**Shielding** of normal tissue is thus as important in attempting curative radiotherapy as is irradiation of the tumor. Insofar as is possible, all normal tissue, particularly lung, heart, bone marrow, liver, and kidneys, must be shielded from treatment fields. If an exploratory laparotomy is performed, the spleen should be removed, not only to examine it for HD, but to exclude the necessity for splenic irradiation thus sparing the left kidney and left lower lobe of the lung. Likewise, if the abdomen is explored in female patients, both ovaries should be moved laterally to remove them from the possible treatment field. Individualized lead shields must be constructed for each patient and changes in shielding may be necessary during therapy. For example, large mediastinal masses may require inclusion of much of the lungs in the original treatment field; as the tumor shrinks the treatment field should be reduced by increasing the area of shielded lung. With modern megavoltage machines and with the increasing number of hospitals in the United States that have such machines, delivering a tumoricidal irradiation dose to a patient with HD is rarely a problem. Hopefully, knowledge and technique concerning shielding will grow commensurate with proliferation of irradiation equipment.

Fig 50-13 Comparison of results of treatment of patients with stages I and II Hodgkin's disease with extended field or "total nodal" irradiation. Patients were randomly assigned to treatment schedules; the extended field usually consisted of mantle irradiation. Actual survival curves are shown. The effects of the two types of treatment differed significantly except in patients with nodular sclerosis. (From Johnson et al,<sup>77</sup> courtesy of the authors and Cancer Research.)

**RESULTS OF RADICAL RADIOTHERAPY.** As many as 90% of patients with stages I and II-A HD may be cured by radical radiotherapy (Figs. 50-13 and 50-14), although some reports are not quite so promising.<sup>128,158</sup> With stages I-B and II-B the prognosis is not quite as bright, but more than half of the patients in these stages appear to be cured (Figs. 50-13 and 50-14). In patients with stage III-A, cure is achieved in somewhat less than 50% and most of those with III-B have experienced relapse within three to four years.<sup>75</sup> For this reason we and many others recommend radiation as initial therapy for patients having stages I to III-A and chemotherapy initially for those having stages III-B and IV. Alternatively, for those advanced stages, combination chemotherapy-radiotherapy can be employed (page 1561). As previously discussed (page 1553), the frequency of relapse in part depends upon pathologic classification (Table 50-10).

### Palliative Radiotherapy

In the patient in whom cure no longer seems possible, radiotherapy is still of benefit although chemotherapy is preferable for most of this group. In most patients, delivery of 1000 to 2000 rads will induce significant tumor regression and sometimes tumor disappearance. Radiotherapy may be used to rapidly reduce masses obstructing vital organs, eg, spinal cord compression, bronchial constriction, vena cava obstruction or obstruction of the common bile duct (Chapter 54). When most symptoms are thought to be due to tumor in a single site in patients still pancytopenic following chemotherapy, a modest local dose of irradiation may prove helpful. The practice of "chasing" the tumor with palliative doses of radiotherapy has been largely supplanted by chemotherapy.

### "Curative" Chemotherapy

The results of the original trial of the four-drug regimen known as "MOPP" (Table 50-11) suggest that some of the patients may have been cured.<sup>39,40</sup> Of 43 patients entered in the study by July 1967, there

were three with stage III-A disease, five with III-B, four with IV-A, and 31 with IV-B; thus extensive disease was present in all. There were two drug-related deaths. The remaining patients improved, 81% achieving complete remission (no evidence of residual disease) and, four or more years after stopping therapy, 43% of those who had achieved complete remission were still free of evident disease.<sup>24</sup> The pattern of relapse approximates that seen after irradiation therapy (Fig. 50-10). Although caution must be exercised in considering these patients as having been cured there is reason to think that this is a possibility. Results of comparable studies indicate a similar complete remission rate, but follow-up periods to date have been too short to allow assessment for the possibility of cure. Preliminary reports of trials of other drug combinations indicate that the incidence of complete remissions is no higher than with "MOPP" and relapse occurred after a short interval in a larger number of patients.<sup>159</sup> Substitution of vinblastine for vincristine in the regimen led to an apparent increase in degree of leukopenia without an appreciable increase in rate of remission.<sup>114</sup> Periodic re-induction doses of "MOPP" may delay relapse,<sup>51</sup> but whether such therapy is preferable to withholding such "maintenance" therapy and then attempting re-induction of

remission after relapse has developed is not yet known. "MOPP" therapy in patients relapsing after radiotherapy has resulted in a percentage of remissions approximating that obtained in untreated patients.<sup>21,51,101,111</sup> However, when an extensive history of chemotherapy preceded MOPP, the rate of remission was quite low, particularly when resistance to drugs in the regimen had been noted before their use in the regimen.<sup>51,101,114</sup> Radiotherapy did not appear to predispose to a significant increase in bone marrow toxicity when "MOPP" was given subsequently.<sup>24,151</sup> However, it must be kept in mind that permanent fibrosis of bone marrow has followed 3500 rads<sup>153</sup> and three to six months have generally been required for recovery of normal marrow function following irradiation.<sup>56</sup>

Thus, for the present, "MOPP" therapy appears advisable for all patients in stage IV when first treated and perhaps in III-B as well as for patients relapsing after attempted curative radiotherapy. There is no contraindication to MOPP therapy. However, contrary to the recommendation of DeVita and Carbone,<sup>39</sup> it seems reasonable to recommend reducing the dose of nitrogen mustard (HN2) and procarbazine in the presence of neutropenia or thrombocytopenia, as shown in Figure 50-15. The patient described there illustrates the dramatic results that can be obtained with combination chemotherapy. Beginning with small doses of procarbazine and HN2 and full doses of vincristine and prednisone this patient improved with each course and remained in complete remission for two years.

Not all patients are responsive to combination chemotherapy or to irradiation and complete remission is never achieved in a few.

If it should prove that a significant number of patients with stages III-B and IV are cured by combination chemotherapy, then its possible use as a substitute for radiotherapy in more localized disease will need to be considered. Consequently, the results of its use for all stages of HD where radiotherapy is not available are of special interest.<sup>117</sup> In a preliminary report of a small series of pa-

proportion of the lung must be irradiated also. One or two courses of MOPP therapy given before irradiation may reduce the mass to the point at which much of the lung may be shielded during subsequent radiation therapy. Preliminary reports of combined radiotherapy-chemotherapy suggest that "curative" radiotherapy can be followed by a full course of MOPP without intolerable toxicity occurring.<sup>109,136a</sup> On the other hand, severe hematopoietic depression was reported in one study in which intensive chemotherapy was followed by radiotherapy.<sup>65a</sup>

### Palliative Chemotherapy

Since the introduction of *nitrogen mustard* (HN2)<sup>164</sup> a number of chemotherapeutic agents that are useful in the treatment of HD have been developed.<sup>12,158</sup> (Chapter 55). These can be classified as (1) alkylating agents such as HN2,<sup>19,71</sup> chlorambucil,<sup>48</sup> and cyclophosphamide<sup>71</sup>; (2) the vinca alkaloids, vinblastine (VLB)<sup>6</sup> and vincristine (VCR)<sup>25</sup>; (3) the methylhydrazine derivative procarbazine<sup>18</sup>; (4) adrenocorticosteroids<sup>59</sup>, and (5) agents still considered experimental such as bleomycin, BCNU,<sup>96</sup> and streptozincin.<sup>57</sup>

The frequency of improvement with most of these agents when used singly is quite similar (Table 50-12). Complete remission is much less common than following combination chemotherapy, although apparent "cures" have been reported.<sup>90</sup> The quality of response depends, at least in part, on the dosage employed. Maximally tolerated doses of drugs used as single agents produce a higher frequency of response than do smaller doses, but at the expense of increased morbidity due to drug toxicity.<sup>52</sup> In general, response to a new agent in patients who have received extensive prior chemotherapy is less good than occurs when that drug is used early in the course.<sup>52</sup> Whether this is due to lower drug tolerance or to intrinsically more resistant disease is not entirely clear. However, in a controlled crossover type of study, response to VLB and HN2 was the same regardless of the order in which they were used.<sup>6</sup> Remissions following the use of single agents usually are short without additional

†Complete remission was defined by stricter criteria in the group receiving combination chemotherapy than in most groups receiving single-agent therapy. Thus, the difference between percentage in complete remission following combined versus single agent therapy is probably underestimated.

therapy, but they can be maintained for some time by continuing the use of the drug (Table 50-13). Selected dosage schedules of various drugs used as single agents are presented in Table 50-14.

*Drug resistance* is judged to be present when less than 50% tumor regression occurs with standard dosage or when the tumor begins to grow while the patient is on full-dose maintenance therapy. Larger doses may still result in reduction of tumor, but bone marrow toxicity increases commensurate with the increased dose and may become prohibitive. Resistance to one alkylating agent usually signifies resistance to all alkylating agents, but whether there is cross resistance between VCR and VLB is less certain. Resistance to alkylating agents and VLB does not imply resistance to procarbazine.<sup>38</sup>

It is now a common practice to initiate chemotherapy with "MOPP" and to use this until the patient proves resistant. Consequently, the drugs available to the "MOPP"-resistant patient are limited to VLB or experimental agents such as bleomy-

**Table 50-13. Other Results of Therapy with Drugs Used Singly\* and Duration of Remissions in HD**

Drug	Number of Patients	Percent Improved†	Duration of Response (Mean)	
			Therapy Unmaintained (Months)	Therapy Maintained (Months)

cin, BCNU, and streptomyacin (Chapter 55). Prednisone still may be useful in the "MOPP" resistant patient since it is given for a short time only in the "MOPP" regimen (Table 50-11).

During symptomatic therapy it is important to keep in mind the general principles of such therapy. These emphasize the objectives of keeping the patient as comfortable as possible (Chapter 55). Thus, if the patient

**Table 50-14. Suggested Dosage Schedule for Single-Agent Therapy in Hodgkin's Disease**

Agent	Daily Dose	Frequency of Dose	Duration
Nitrogen mustard	0.3–0.4 mg/kg iv or 0.1 mg/kg/day for 4 days <sup>117</sup>	Two consecutive doses every 4–6 weeks	Until all evidence of disease disappears or drug resistance supervenes
Chlorambucil	0.1 mg/kg, orally	Daily	Until all evidence of disease disappears or drug resistance supervenes
Cyclophosphamide	2 mg/kg, orally or 40 mg/kg as single iv dose	Daily	May be continued at reduced dose as maintenance therapy
Vinblastine	0.15 mg/kg iv (increase until leukopenia occurs)	Weekly	Relapse occurs quickly if therapy is stopped; interval between doses can be lengthened
Vincristine	1.4 mg/m <sup>2</sup> (not to exceed 2 mg total)	Once a week	Repeat dosage until resistance appears or toxicity develops
BCNU	100 mg/m <sup>2</sup> daily X 2, iv	Every 4–6 weeks	Repeat dosage until resistance appears or toxicity develops
Prednisone	60 mg/day	Daily	Stop in 4–6 weeks

is asymptomatic or relatively so, no therapy may be advisable. In this case the presence of palpable HD does not in and of itself demand therapy since eradication of the disease is no longer considered possible. If drugs are considered for use in doses calculated to induce toxicity, this must be done with the anticipation that the symptomatic benefit to be achieved will more than counterbalance the period of increased discomfort induced by therapy. Adjunctive therapy (Chapter 54) is quite important in palliation; eg, control of fever by indomethacin<sup>143</sup> may improve the patient's well-being significantly.

**INADEQUATE INITIAL THERAPY.** Unfortunately many patients with HD are not being staged carefully and still receive palliative radiotherapy or chemotherapy at the time of diagnosis. Still others with relatively slowly progressive disease were treated in this fashion some years ago and are only now showing signs of relapse. Deciding how to manage such patients constitutes a difficult problem. There are no data to suggest that curative radiotherapy can be given safely and successfully to patients relapsing from an initial course of irradiation. It seems reasonable, however, to treat such patients with "MOPP."

*Patients in whom no modality of therapy proves to be of much benefit remind us that while the outlook for the patient with HD has improved, the problem is by no means solved.*

- Cutaneous Lymphoma
- Mycosis Fungoides
- Sézary's Syndrome
- Burkitt's Lymphoma
- Histiocytic Lymphomas
- Leukemic Histiocytic Lymphomas
- Histiocytic Medullary Reticulosis

THE non-Hodgkin's lymphomas (NHL) represent the malignant tumors of lymphoid tissue, excluding Hodgkin's disease (Chapter 50) and the lymphoid leukemias (Chapters 47 and 49). They can occur in individuals of any age although they are exceedingly rare in children younger than two years<sup>109,113</sup>, all types become increasingly frequent as age advances (Chapter 46). These lymphomas are more common in males than in females (Chapter 46).

### Classification

Since the non-Hodgkin's lymphomas were first recognized as a distinct group (Chapter 46)<sup>46,59,103,109</sup> a variety of classifications have been proposed but none is entirely satisfactory. The cells that infiltrate the nodes and other tissues in NHL are forms of lymphocytes and histiocytes ("reticulum" cells), but the degree of differentiation of these cells as judged by histologic criteria differs from patient to patient; the cell type may be relatively uniform or a mixed population may be present and the cells may be arranged in a diffuse or in a nodular (follicular) pattern. The ideal classification of the NHL would be reproducible in the judgment of different observers and each subclass would be expected to differ from the others with respect to clinical manifestations, response to therapy, and prognosis. Three schemes of classification in particular have enjoyed some popularity—those of Craver,<sup>109</sup> Gall and Mallory,<sup>59</sup> and Rappaport<sup>103</sup> (Table 51-1). That of Rappaport is the most recent and is now in vogue, but earlier classifications must be understood in order to appreciate much of the earlier literature.

The classification popularized by Craver and others<sup>109</sup> was based on a division of NHL into three broad categories—lymphocytic lymphosarcoma (LLSa), reticulum cell sarcoma (RCSa), and giant follicle lymphosarcoma (GFLSa). The advantages of this

**Table 51-1. Alternative Classifications of Non-Hodgkin's Lymphoma and the Approximate Relationships of the Various Groups**

Craver <sup>109</sup>	Gall and Mallory <sup>89</sup>	Rappaport <sup>105</sup>
Lymphocytic lymphosarcoma (LLSa)	lymphocytic lymphoma	lymphocytic well differentiated
Reticulum cell sarcoma (RCSa)	lymphoblastic lymphoma stem cell lymphoma clasmatocytic lymphoma	lymphocytic poorly differentiated undifferentiated histiocytic differentiated mixed lymphocytic histiocytic
Giant follicle lymphosarcoma (GFLSa)	follicular lymphoma	follicular (nodular) (this term is added to the primary designation of any of above types in which a follicular pattern predominates)

classification are its simplicity and the demonstrated clinical differences between the three subtypes. Its drawbacks include the fact that, in GFLSa, the type of cells making up the giant follicles are not uniform and in later stages the follicular structure may be lost. Less striking degrees of follicle formation may be present in the other categories of lymphoma and their clear separation from GFLSa may therefore be difficult. As to RCSa, cases not fitting LLSa or GFLSa often have been classed as RCSa. As discussed in Chapters 6 and 8, the term "reticulum cell" is not a very satisfactory one.

Gall and Mallory<sup>89</sup> suggested that five categories of disease could be recognized—lymphocytic, lymphoblastic, stem cell, clasmatocytic, and follicular lymphoma. They reviewed the records of 389 patients and searched for clinical differences between the different types. A number of minor differences of questionable significance were noted, but the major ones related to duration of survival, spleen size, and leukemic conversion. Follicular disease was associated with the longest survival, followed by lymphocytic and, in turn, by stem cell, clasmatocytic, and lymphoblastic lymphoma. There was little difference in survival rates among subjects having the last three pathologic types. Leukemic conversion was most common in patients with the lymphocytic variety; un-

common in those with the stem cell, clasmatocytic, or follicular types; and intermediate in incidence in those having the lymphoblastic form. Splenomegaly was encountered most frequently in patients with the lymphocytic type, and in descending frequency in those with the lymphoblastic, follicular, clasmatocytic, and stem cell types. Thus, there were clinical as well as pathologic differences in Gall and Mallory's five categories, but differentiation of the lymphoblastic-stem cell-clasmatocytic types was on less solid clinical grounds than the separation of these from GFLSa and LLSa. In another study,<sup>90</sup> undifferentiated RCSa was found to be similar to histiocytic RCSa in most respects, including prognosis, but was more likely to undergo leukemic conversion and less likely to be associated with skin involvement.

Rappaport and associates<sup>106</sup> proposed that the nodular (follicular) varieties of disease be subdivided into distinct cell types rather than considering GFLSa as an entity. The distribution of cases classified according to the Rappaport classification as compared with that of Craver is shown in Table 51-2. They pointed out that a nodular or a diffuse pattern may be seen in each of five cellular types, which they named well-differentiated lymphocytic, poorly differentiated lymphocytic, undifferentiated, histiocytic differentiated,

and mixed lymphocytic-histiocytic. A nodular pattern is most commonly observed in the poorly differentiated lymphocytic (Fig. 51-2) or mixed cell types.<sup>75</sup> In all varieties of NHL, a follicular pattern implied a better prognosis than did a diffuse one,<sup>106</sup> confirming the original observations of Brill and co-workers<sup>25</sup> and Symmers.<sup>129</sup> Survival was found to be distinctly superior in the well-differentiated lymphocytic-follicular type as compared with the other follicular varieties.<sup>106</sup> However, this has not been the experience of some other investigators.<sup>104</sup>

The Rappaport classification is being adopted by many institutions, but whether all of the categories will prove to be useful remains to be determined. In the study of clinicopathologic correlations in 223 patients summarized in Table 51-2,<sup>75</sup> differences between some, but not other, categories were apparent. Any degree of nodularity was found to confer a better prognosis than was noted with any diffuse variety (Table 51-3). Nodular forms were uncommon in children and young adults as compared to their occurrence in older patients, and they tended to be more common in males than in females. Extra-lymphatic spread, as well as systemic symp-

toms, was more common in patients with the diffuse types than in those having the nodular varieties. With regard to differences between lymphocytic, mixed, and histiocytic varieties (within either diffuse or nodular categories), patients with the lymphocytic and mixed forms survived longer than those with the histiocytic forms. Bone marrow involvement was more common in those with the lymphocytic type.

In a patient with NHL, when the pathologic picture changes with time, the change usually is toward a more undifferentiated form of disease, as from LLSa to RCSa,<sup>38</sup> or GFLSa to LLSa or RCSa.<sup>20</sup> Gall and Mallory<sup>59</sup> noted a changing pathologic picture in 23% of 84 patients studied serially, the change being always toward a more undifferentiated picture. In patients with follicular disease, approximately one half lose the follicular pattern and acquire a lymph node picture of diffuse, unstructured cellular infiltration at death.<sup>106</sup> Conversion from a pathologic picture of any form of NHL to a picture of Hodgkin's disease or vice versa is most unusual, if it ever occurs.<sup>59,103</sup>

In general, in adults, LLSa, probably is the most common disease form, being more

common than RCSa in some studies<sup>45,67</sup> and about equally common in others<sup>109</sup>; GFLSa is least common, making up approximately 10% of all NHL<sup>67,109</sup> or even less.<sup>45</sup> In chil-

dren, RCSa, especially the lymphoblastic variety, is more common than LLSa.<sup>7</sup> While GFLSa may be observed in children,<sup>7,20</sup> it makes up an even smaller proportion of the cases than in adults.<sup>109</sup>

## Histologic Patterns of Non-Hodgkin's Lymphoma

Destruction of the normal nodal architecture, the presence of pseudo-follicles, invasion of the capsule with extension into the adjacent fat, and the presence of neoplastic cells either in the pulp, the sinuses, or within pseudo-follicles are the usual criteria for histologic diagnosis in excised lymph nodes. Portions of the node may appear normal. As noted elsewhere (Chapters 40 and 50), in

patients who eventually develop malignant lymphoma the initial biopsy specimen or specimens may be reported as representing "reactive hyperplasia,"<sup>43</sup> perhaps because the specimen is from a non-involved node.

*Well-differentiated lymphocytic lymphoma* is characterized by the presence of cells that resemble the normal small lymphocyte. The infiltration is quite uniform and there are few mitotic figures. The uniform cellular infiltration obscures nodal architecture, but the nodal capsule may be intact.

*Poorly differentiated lymphocytic lymphoma* (lymphoblastic lymphosarcoma), the most undifferentiated form of which is included under RCSa in the Craver classification, is made up of cells that do not conform entirely to the characteristics of a lymphoblast, as seen in the blood of patients with lymphoblastic leukemia (Chapter 47). The cell is 10 to 20  $\mu$ m in diameter. The nucleus is centrally placed and round or slightly indented and possesses a distinct border. It is made up of chromatin that is evenly distributed and less clumped than in a lymphocyte. Nucleoli may or may not be evident. There is a uniformly narrow basophilic rim of cytoplasm, spherical in outline or irregular. Mitotic figures may be seen.

*Undifferentiated and differentiated forms of histiocytic lymphoma* are distinguished. In the *undifferentiated or syncytial form*, the predominating cell is relatively large (diameter of 15 to 35  $\mu$ m) with varying amounts of cytoplasm that frequently is scanty and pale staining. A syncytial arrangement often prevails. The nucleus is vesicular and is about two to four times as large as that of a lymphocyte. It is round or oval in shape or slightly indented. The chromatin appears delicate; it is irregularly distributed and lacks points of condensation. There is a thin, but distinct, nuclear membrane and a single, prominent, dark-staining nucleolus. Reticulum fibers are scanty and are mostly limited to preexisting stroma. There is little evidence of histiocytic or lymphocytic differentiation. The *differentiated or histiocytic form* (Fig. 51-2) is composed predominantly of neoplastic histiocytes that possess the power of

phagocytosis, fibril formation, or both. The cells are smaller than in the undifferentiated form, but are larger than lymphocytes, being 15 to 20  $\mu$ m in diameter. The nucleus often is eccentric; it may be round but more often is oval, reniform, or horseshoe-shaped. The chromatin is fine and nucleoli are rare. The cytoplasm is abundant, generally eosinophilic, and the borders tend to be irregular in outline, suggesting ameboid propensities. Engulfed particles and sometimes whole cells may be found in the cytoplasm.

*Malignant lymphomas of the mixed cell type* are characterized by a neoplastic proliferation of histiocytes and lymphocytes without appreciable predominance of either cell type. These often exhibit a follicular pattern.<sup>108</sup>

Any of the above-mentioned cellular types of NHL may assume a follicular pattern. The diagnosis of *follicular or nodular lymphoma* rests on the presence of large pseudo-follicles rather than upon a specific cell type (Fig. 51-3); any residual normal glandular tissue is compressed by the large and often confluent follicles. Trabeculae are obscured and there is a stromal rearrangement unlike that seen in normal lymph node hyperplasia. The follicles are larger and more numerous than those usually observed in simple hyperplasia. Their close-packed arrangement, their relatively uniform size, together with their distribution throughout the node, rather than being limited to the cortex, and the condensation of the reticulum, help to distinguish them from what is seen in simple hyperplasia. In some series,<sup>73</sup> any degree of nodularity, even if it involves only part of a node, and even very subtle nodularity requiring special stains to demonstrate "nodules" delineated by compressed reticulum fibers surrounding them, have been considered sufficient to classify the lymphoma as follicular.

Differentiation of benign and lymphomatous infiltrations can be quite difficult (pages 1552 and 1585, Chapter 40). This is particularly true of well-differentiated NHL with or without a follicular pattern. First and two other pathologists reviewed material from 40 patients in whom the original diagnosis was GFLSa, but all three were in

Fig. 51-2. Histiocytic lymphoma, diffuse type. Nodal architecture is obliterated by a diffuse infiltration of histiocytes (Lymph node H & E stain 160 $\times$ ) (Courtesy of Dr. R. W. McDivitt)

Fig. 51-3. Follicular lymphoma. Lymph node ( $\times 60$ ) (Mayer and Thomas,<sup>90a</sup> courtesy of Bulletin of Johns Hopkins Hospital)

agreement in only 22 instances.<sup>56</sup> They also noted that "considerable variation occurred in the check sheets from day to day when the same pathologists reviewed the same slides."

The relative frequency of the various histologic types of NHL is shown in Table 51-4.

## Mode of Presentation

Most patients with NHL are first seen with disease primarily in lymph nodes. The most common initial complaint is enlarged lymph nodes. Generally there are no systemic symptoms. The nodes usually, but not invariably, are painless and often have been noted in cervical or supraclavicular areas. Fatigue, malaise, weight loss, fever, or night sweats were noted in only 2 to 14% of patients in one series (Table 51-5), although, in a more recent series, fever and/or night sweats were present in 24%.<sup>73</sup> These symptoms are more common in patients whose disease is widespread than in those with more localized disease.<sup>73</sup> Pruritus,<sup>109</sup> a prominent symptom in patients with Hodgkin's disease (Chapter 50), is uncommon. Abdominal pain, nausea and vomiting, and dysphagia, resulting from gastrointestinal involvement or enlarged

Mediastinal or hilar nodes	1%	3%	4%
Bone lesions	0%	8%	1%

\*Modified, from Rosenberg et al.<sup>109</sup>

retroperitoneal nodes, are unusual. Pain from bone lesions is uncommon except in children.<sup>113</sup> A variety of other complaints are encountered occasionally, reflecting the unusual forms of presentation (page 1584 and Chapter 54). For example, shifting pulmonary infiltration associated with eosinophilia (Loeffler's syndrome) has been the presenting feature.<sup>6a</sup> On the average, patients have been aware of enlarged lymph nodes for six months before consulting a physician.<sup>109</sup>

The manifestations and course of patients who, when first examined, have NHL that is apparently confined to nonlymphoid tissue are somewhat different and will be discussed in a later section (page 1584).

## Physical Findings

Enlarged lymph nodes (Fig. 51-4) are present in most patients with NHL and are especially common in those with GFLSa (Table 51-5). Cervical or supraclavicular nodes are most often involved. Fewer than 5% of patients have generalized adenopathy.

The nodes usually are nontender, freely movable, distinct, and rubbery, although in some patients with RCSa they are quite hard. Spontaneous fluctuations in the size of lymph nodes may be observed.<sup>6,129</sup> Tonsils and/or adenoids are visibly enlarged in about 10% of patients with LLSa, but are less commonly enlarged in those with GFLSa<sup>109</sup> (Fig. 51-5).

*Röntgenograms* of bone in those complaining of bone pain or tenderness usually disclose lesions (Chapter 54). Chest x ray revealed hilar or mediastinal nodes in a very small percentage of patients in one series (Table 51-5), but, in another series, evidence of mediastinal or hilar disease was found in 18% of patients with nodular lymphoma and in 24% of those with diffuse lymphoma.<sup>75</sup> Parenchymal lung involvement is rare at the time of diagnosis.<sup>109</sup> Retroperitoneal nodes may be palpable, but the spleen and/or liver are enlarged in only a small percentage of patients at the time of diagnosis.<sup>38,109</sup> *Splenomegaly* as the only sign of disease was noted in 2.5% of patients with GFLSa, but was present in fewer than 1% of those with LLSa or RCSa.<sup>109</sup> (See primary NHL of spleen, page 1585.)

Disease localized to a single lymph node region or to two contiguous lymph node regions (stage I disease) is unusual.<sup>2a,46</sup> In one series,<sup>45</sup> only 25% of patients had localized nodal disease detectable on physical examination, and, in a series of patients subjected to more extensive staging procedures, stage I or I<sub>E</sub> (extension to nonlymphoid tissue from a local involved node) was found in 12%.<sup>75</sup> In patients with stage I or II disease, lymphangiography revealed abdominal node involvement in 20%<sup>76a</sup> to 80%.<sup>83</sup> Local node disease may be most common in patients with GFLSa; in one study, 34 of 64 of these patients had disease apparently limited to one node group, but extensive staging procedures were not performed.<sup>56</sup> When NHL was classified as "diffuse" or "nodular" on the basis of any degree of nodularity constituting the latter, stage I was slightly more common in patients with "diffuse" (14%) than in those with "nodular" disease (11%).<sup>75</sup>

Fig 51-4 Extreme generalized adenopathy in a patient with "reticulum cell" sarcoma. The radiosensitivity of the tumor is indicated by the change produced in 13 days.

Fig 51-5 Nasopharyngeal tumor in a patient with follicular lymphoma. The uvula is displaced to the right.

Laboratory Findings<sup>20,59,109</sup>

Examination of the *blood* reveals normal values for blood cells in most patients at the time of diagnosis. Increased leukocyte counts are uncommon, as is leukopenia (Table 51-6). However, abnormal-appearing lymphocytes (page 1580) may be present in small numbers in a few patients<sup>20,109</sup> and these may lead one to suggest NHL as a cause of lymphadenopathy. Anemia is present in fewer than 50% of patients and is rarely severe at diagnosis, although Coombs'-positive hemolytic anemia may occur, especially in well-differentiated lymphocytic lymphoma (Chapter 54). The anemia usually is due to decreased production as evidenced by low reticulocyte numbers. Significant thrombocytopenia is unusual (Table 51-6).

In one study, *bone marrow* biopsy performed at the time of diagnosis revealed evidence of NHL involving the bone marrow in 18% of 356 patients.<sup>75</sup> In that series, marrow was involved somewhat more frequently in those with the nodular than in those having the diffuse varieties (22% vs 15%); marrow involvement was found in only 10% of patients with the histiocytic type, in 14% of those having the mixed type, and in 33% of those with the poorly differentiated lymphocytic variety. Of 12 patients with the well-differentiated lymphocytic type the bone marrow was involved in 42%. In another

study of marrow biopsy in 75 patients with well or poorly differentiated lymphocytic lymphoma, 63% had evidence of marrow invasion.<sup>137a</sup>

On biopsy in patients with marrow involvement, nodular accumulations of small lymphocytes are noted in those with the well-differentiated lymphocytic form and lymphoblasts and "reticulum" cells in those with the other varieties. In aspirates the percentage of lymphocytes may be increased in the former group or the finding of abnormal-appearing cells in the latter may allow one to make a diagnosis. Occasionally, in patients with anemia, often accompanied by leukopenia, neutropenia, and/or thrombocytopenia and no palpably enlarged lymph nodes or spleen, aspiration of bone marrow may reveal a marked increase in small lymphocytes. In such subjects, a diagnosis of well-differentiated lymphocytic lymphoma, apparently limited to bone marrow, must be considered but is difficult to establish without biopsy.

*Uric acid* may be increased in serum or urine, but more often is normal (Chapter 54). Hypercalcemia almost always is an indication of x-ray demonstrable destructive bone lesions.<sup>95</sup>

*Serum proteins* usually are normal when the diagnosis is made. However, hypoalbuminemia often develops as the disease advances and reduced levels of gamma globulin may be found, especially in patients with well-differentiated lymphocytic lymphoma, although with a lower frequency than in those with CLL<sup>22</sup> (Chapters 44, 54). Monoclonal paraprotein spikes without other evidence of myeloma or related diseases (Chapters 52 and 53) are seen occasionally.<sup>79</sup>

## Diagnosis and Differential Diagnosis

The diagnosis is made by observing the characteristic pathologic changes in biopsy material (page 1571), usually from excised lymph nodes but occasionally from other sites such as tonsils, bone marrow, spleen, liver, bowel, or skin.<sup>109</sup>

Table 51-6. Blood Values in Non-Hodgkin's Lymphoma at the Time of Diagnosis\*

	Percent of Patients
Hemoglobin	
Greater than 14 g/dl	40
12-13.9 g/dl	38
8-11.9 g/dl	20
Less than 8 g/dl	2
Leukopenia (less than $4.0 \times 10^9/l$ )	3
Platelets	
Greater than $200 \times 10^9/l$	60
100-200 $\times 10^9/l$	35
Less than $100 \times 10^9/l$	5

\* Adapted from Rosenberg et al.<sup>109</sup>

Difficulty in diagnosis is encountered in some 2 to 4% of patients who have no palpable evidence of disease and in whom the chest film shows no abnormality. Such patients may consult a physician because of fever, night sweats, or weight loss and in them the retroperitoneal nodes are often the site of disease.<sup>43,109</sup> When the primary finding is severe anemia, especially when accompanied by neutropenia and thrombocytopenia, bone marrow aspiration or, preferably, biopsy may disclose NHL. Such patients eventually may develop palpable lymphadenopathy or leukemic transformation may occur (page 1579), but others may die from infection or hemorrhage secondary to neutropenia and thrombocytopenia, respectively, while the NHL is still apparently limited to the marrow.<sup>92</sup>

There are numerous conditions, both benign and malignant, that are associated with symptoms, signs, and laboratory findings similar to those observed in NHL. The differential diagnosis depends upon the histologic features of NHL as distinguished from those of other causes of lymph node or lymphatic tissue enlargement or infiltration (Chapters 7 and 40). The demonstration of IgG on the cells in germinal centers may be helpful in distinguishing benign from malignant follicular hyperplasia.<sup>21a</sup> If examination of the blood discloses CLL, no additional diagnostic steps are necessary (Chapter 49). If blood lymphocytes are not increased, excisional biopsy of palpably enlarged lymph nodes is the next step to consider. In some patients, as mentioned above, bone marrow aspiration and/or biopsy may disclose marked lymphocytic infiltration or abnormal-appearing cells that suggest the diagnosis (see Chapter 40 for a more detailed discussion of diagnostic steps).

If a skilled pathologist considers the tissue to be clearly indicative of NHL, then, unless the patient has received diphenylhydantoin, related hydantoins (page 1553),<sup>62</sup> or perhaps other drugs, little doubt exists as to the diagnosis, for few or no other benign conditions mimic the pathologic manifestations of NHL. The opposite situation, in which an excised

node is considered nondiagnostic in a patient who eventually proves to have lymphoma, is much more common<sup>43</sup> and was discussed in Chapters 40 and 50. For differentiation between tropical splenomegaly and primary lymphoma of the spleen see pages 1411 and 1586.

As previously discussed (Chapter 49), no pathologic distinction between LLs and CLL has been demonstrated other than blood lymphocytosis in the latter.

## Course and Survival

Therapy (page 1581), while it may not always prolong life, nonetheless provides symptomatic relief and significantly modifies the expression of disease throughout its course. Thus, extreme enlargement of lymph nodes (Fig. 51-4) rarely is seen in treated patients. However, by the time death occurs, cervical, axillary, thoracic, and abdominal lymph nodes are involved in most patients with NHL and in approximately 50% of them the liver, spleen, and parenchyma of the lungs or kidneys are involved.<sup>109</sup> Spread of disease to virtually all organs can be observed at autopsy.<sup>59,103,109</sup>

### Causes of Death

An exact, identifiable single event often is lacking as an explanation for death. Many patients become increasingly debilitated with widespread lymphoma involving many sites and die without a clear-cut single cause. Death from bacterial infection is relatively common and death from fungal infection may occur (Chapter 54). In some patients the infection is attributable to deficient antibody production (Chapter 44), most commonly in the well-differentiated lymphocytic form of NHL (Chapter 54). In others, infection begins in tissue damaged by lymphomatous infiltration, eg, pneumonia secondary to parenchymal pulmonary disease. Since the tumor often is poorly responsive to chemotherapy as death approaches, attempts to control its growth with large doses of chemotherapeutic agents often induce neutropenia, contributing to the frequency of infection.

Neutropenia also may develop as a consequence of bone marrow invasion. Thrombocytopenia may have the same cause as neutropenia; death from thrombocytopenic hemorrhage is observed occasionally. In still other patients, death is attributable to organ failure secondary to lymphomatous infiltration of such tissues as lung, gut, kidney, or meninges (Chapter 54).

### Survival

Survival curves for NHL fit a log probability plot reasonably well.<sup>109</sup> This type of survival curve is common in many types of cancer, but does not describe survival well in other lymphoid neoplasms such as CLL (Chapter 49). Rosenberg et al<sup>109</sup> studied survival in 1269 patients whose lymphoma was classified by the method of Craver (Table 51-7). Of these patients, 50% survived longer than 26 months, and 28% survived for five years or more. Prognosis was much poorer in children than in adults and was slightly

better in females than in males. Those with disease apparently limited to one lymph node area lived significantly longer than those with more extensive disease. Patients with GFLSa lived approximately three times as long as those with LLSa or RCSa. Whether the better results in patients with disease that initially was localized reflected a high frequency of GFLSa was not determined. Gall and Mallory<sup>59</sup> reported longer survival in patients with well-differentiated GFLSa than in those whose follicles contained poorly differentiated cells, and an average survival for all patients with GFLSa of five years as compared to three years for those with LLSa and one or two years for patients with all other forms of disease. Others also found the median actuarial survival of GFLSa patients to be approximately five years<sup>20</sup>; the clinical extent of the disease was found to be more important than fine morphologic distinctions. In still other studies,<sup>86,87,104</sup> the prospects for survival also were best in GFLSa, intermediate in LLSa, and shortest in RCSa.

Survival, as determined in some series,<sup>59,86,87,101,109</sup> is probably underestimated by virtue of the statistical methods used in calculations. As discussed for CLL (Chapter 49), some forms of calculation by actuarial methods give a fairly accurate figure for expected survival. Such calculations for patients with NHL, treated during the past decade<sup>75</sup> (Fig. 51-6A and B), suggest the following median duration of survival: lymphocytic, poorly differentiated and mixed cellularity, diffuse varieties, two years; nodular varieties, seven to eight years; histiocytic, diffuse, one year; nodular, three to four years. The number of patients with well-differentiated lymphocytic<sup>16</sup> and undifferentiated<sup>14</sup> types was too small to derive a meaningful median survival, but the data suggested that the longest survival period was in the former group and the shortest in the latter.

Thus, of the various possible histologic types, nodularity appears to be the single most important factor influencing survival.

The above figures represent approximations of what may be expected of a large group of patients. However, the behavior of

<sup>a</sup>Onset of symptoms or from diagnosis in asymptomatic patients (Modified from Rosenberg et al<sup>109</sup>)

Fig 51-6 Actuarial survival of patients with non-Hodgkin's lymphoma treated at Stanford University, 1960-1971. The number in parentheses after each cell type indicates the number of patients in that group. Not shown are curves for the small number of patients with lymphocytic well-differentiated, diffuse (10), or nodular (B) lymphoma or with undifferentiated lymphoma (14). (From data of Jones et al.<sup>15</sup>)

these tumors varies greatly and survival is so different from one to another patient with an apparently similar tumor that these figures provide little help in estimating prognosis in individual cases.

In addition to age, sex, cell type, and apparent extent of disease (Table 51-7), other factors present at diagnosis may influence survival. Lymphopenia appeared to imply a grave prognosis in one series.<sup>109</sup> Median survival in patients with fewer than  $1.0 \times 10^9$  lymphocytes/l was three months; with  $1.0$ – $2.0 \times 10^9$ /l, nine months; and in those with more than  $2.0 \times 10^9$ /l, 18 months. In another series,<sup>75</sup> mediastinal involvement tended to connote a poor prognosis, but the presence or absence of fever and/or night sweats had no prognostic significance independent of that conferred by the extent of demonstrable disease. The influence of age varied according to cell type; no age effect was apparent in patients with diffuse histiocytic disease, young patients living longer than older patients with poorly differentiated lym-

phocytic or mixed cell types of the nodular variety, while the opposite was true in patients whose cell types were of the diffuse variety.<sup>75</sup> The type of detailed analysis of factors influencing survival that has been carried out in the leukemias (Chapters 47-49) and in Hodgkin's disease (Chapter 50) has not been made in NHL.

#### Leukemic Conversion of NHL (Lymphosarcoma Cell Leukemia, LSCL, Leukolymphosarcoma)

Overall survival from onset of NHL was not appreciably different for patients who did or did not develop leukemia, according to one study.<sup>109</sup> However, the prognostic implication of such a change depends on the nature of the leukemia. Thus, conversion to a picture of acute leukemia may occur and in this instance, prognosis is relatively poor. If a picture resembling CLL develops the outlook is much less grave.

The type of leukemia that develops is in-

fluenced by age and by the cell type of the original NHL. In patients with LL<sub>Sa</sub>, the lymphocytes in the blood may be indistinguishable from those of patients with CLL. In such patients it is only the knowledge of a preceding nonleukemic phase of NHL that allows one to make a diagnosis of LSCL rather than CLL. Patients with poorly differentiated lymphocytic lymphoma may develop LSCL with cells morphologically indistinguishable from the lymphoblasts of ALL. Again, in certain patients, the leukemic phase of NHL is associated with the appearance of cells that have morphologic features not commonly encountered in other forms of leukemia<sup>114,116</sup> (Fig. 51-7). Isaacs<sup>66</sup> was probably the first to draw attention to this condition. Most typically, these "lymphosarcoma" cells are large lymphocytes with large nuclei, but they possess more cytoplasm than

does the typical lymphoblast. The nuclear chromatin is clumped, and very large, often single, nucleoli are present. The nuclei are round or oval and may have deep clefts. The cytoplasm may stain lightly, deeply, or gray-blue with Romanowsky stains and may contain vacuoles, azurophilic granules, or, occasionally, basophilic-staining granules that appear to be structureless on electron microscopy (personal observation). Rarely, AML<sup>66</sup> or CML<sup>141</sup> may develop in patients with NHL, but whether this is a "conversion," the coincidental occurrence of two different diseases, or the result of therapy is unknown. The ultrastructure of well-differentiated and poorly differentiated lymphocytes in NHL is very similar to that of leukemic lymphocytes,<sup>17,128</sup> as is the fine structure of the nucleoli.<sup>124</sup> It has been suggested that lymphocytes from patients with

Fig 51-7. Leukocytes from lymphosarcoma cell leukemia. Small lymphocytes from a patient with CLL are shown in panel A for contrast with the larger and abnormal appearing "lymphosarcoma" cells in panels B through K. # PLATE XXI

Cells from chronic lymphocytic leukemia and non-Hodgkin's lymphoma (Wright's stain,  $\times 1000$ ) A, B, Chronic lymphocytic leukemia C, Blood and D, E, bone marrow of three different patients with non Hodgkin's lymphoma, the course in patient shown in E was unusually rapid and resembled that of acute leukemia F shows the typical cells found in the blood in patient shown in E

lymphosarcoma may differ from those of patients with leukemia in propionate metabolism<sup>125</sup> and in cytolytic sensitivity to prednisone.<sup>116</sup>

Leukemic conversion of histiocytic lymphomas is uncommon.<sup>84,105,114</sup> When such conversion does occur, the cells invading the blood resemble those seen in the Schilling type of monocytic leukemia (Chapter 47), when examined by light or electron microscopy.<sup>114</sup>

Leukemic conversion of NHL in children is much more common than in adults, but conversion to a CLL-like picture is exceedingly rare in children.<sup>109</sup> Surveys suggest that one third to one half of children with NHL develop a leukemic phase.<sup>5,113</sup> This picture usually develops within a few weeks following the original diagnosis in children,<sup>74</sup> but may not develop for years in adults.<sup>109,114,117</sup> Rosenberg et al<sup>109</sup> found that 13% of children and 7% of adults developed a leukemic phase, but a later survey from the same institution disclosed a still higher frequency in children.<sup>23</sup> It may be inferred that both figures should be looked upon as minimal since cases in the early years of the series may not have been as well studied. In the series cited, leukemic conversion was noted in 13% of patients with LLs, in 9% with GFLs, and in only 2% with RCSs. Other studies bear out the infrequency of leukemic conversion in RCSs, especially the form characterized by well-differentiated histiocytes.<sup>105,106</sup>

Criteria for making a diagnosis of LSCL in a patient with NHL are somewhat arbitrary since a few peculiar-appearing cells can be observed in the blood of many patients. Persistent lymphocytosis exceeding  $5.0 \times 10^9/l$  is the usual finding on which such a diagnosis can be based, but various other criteria have been proposed.<sup>59,105,109</sup> If the blood is involved, the marrow is almost invariably infiltrated, but whether marrow infiltration without blood involvement should be considered leukemic conversion is debatable.

If the leukemic picture becomes one of CLL, little change may be noted in physical

signs or other laboratory values except that the spleen is more likely to be palpable than before such conversion occurred.<sup>109</sup> However, if the picture is one of acute leukemia, then anemia, neutropenia, and thrombocytopenia develop and often constitute the most important problems.

## Therapy

There are insufficient data in the literature to allow a rational choice of therapy in NHL.<sup>24,103a</sup> Radiotherapy to obviously involved areas,<sup>75,104</sup> total body x-irradiation,<sup>73</sup> administration of radioactive isotopes such as <sup>32</sup>P,<sup>47,50</sup> alkylating agents of all types,<sup>60,89</sup> antimetabolites such as methotrexate,<sup>102</sup> stathmokinetic agents such as vincristine and vinblastine,<sup>32,127</sup> procarbazine,<sup>126</sup> bleomycin,<sup>111</sup> streptonigrin,<sup>108</sup> and steroids used daily<sup>53</sup> or in intermittent dosage<sup>31</sup> have all been found useful. Each of these will reduce the amount of palpable or x-ray demonstrable disease in the majority of patients (partial remission) and lead to complete disappearance of apparent disease (complete remission) in some. Disease recurs in a short time in most patients, but may not recur for some years in a small percentage of patients. As discussed below, combining various useful therapeutic agents results in a greater proportion of patients achieving complete remission than do therapeutic modalities used singly, but this may be accomplished at the expense of increased morbidity during therapy as a result of drug toxicity.<sup>49</sup> Both "curative" and palliative therapy deserve consideration.

### "Curative" Therapy

As with Hodgkin's disease (Chapter 50), the patient should be evaluated with the object of attempting curative therapy. If the disease proves to be limited to one lymph node group, a rather rare event<sup>46,50,73</sup> (page 1575), or to one extranodal site, such as the stomach, radiotherapy probably should be considered the treatment of choice.<sup>75,103a</sup> Apparent cures have followed surgical exci-

sion of localized nodal or extranodal disease, but a nonrandom comparison of surgical versus x-ray therapy suggested that the latter was superior.<sup>109</sup> There is no evidence in NHL that the radical, extended field irradiation therapy recommended for Hodgkin's disease (Chapter 50) has any advantage over radiation therapy restricted to the involved areas.<sup>73,104</sup> However, data are presently inadequate to explicitly describe the best form of irradiation therapy for patients with localized NHL.<sup>56,71,72,98,104</sup> In terms of recurrence at an irradiated site, one report<sup>119</sup> suggested that RCSa and LLSa are similar to Hodgkin's disease in that recurrence is rare if 3500 rads have been delivered, but differ in that they recur more commonly if a smaller dose is used. Nevertheless, in patients with GFLSa, which is more radiosensitive, recurrences have been unusual when as little as 2000 rads were delivered.

The difficulty of defining cure of NHL is illustrated in the discussion of gastric (page 1584) or splenic non-Hodgkin's lymphoma (page 1585). Survival in those circumstances bears little relation to the type of therapy employed and relapse may occur many years after the original diagnosis and treatment. Cure of patients with Hodgkin's disease (Chapter 50) can be defined to some degree since results of therapy have been reported in terms of disease-free interval and survival has been compared to that expected in the general population. Similar analyses of results of therapy in NHL are rare,<sup>107a</sup> the usual reports referring to survival rather than disease-free interval.<sup>71,94,98,104</sup> (Fig. 51-6A and B). Since survival with NHL is highly variable, survival reports are difficult to interpret. Small series do indicate an appreciable frequency of disease-free, five-year survival in patients with GFLSa with localized nodal disease treated by excisional biopsy or by x ray in relatively low doses<sup>56</sup> as well as in patients with all types of stage I or II NHL who survived for five or more years following irradiation.<sup>137</sup> In one large series,<sup>73</sup> 215 patients staged as I to III<sub>E</sub> by the Ann Arbor staging classification for HD (Chapter 50), received initial therapy with radiation alone.

Duration of follow-up in the series was not long enough to allow firm guide lines to be drawn, but certain tentative conclusions were reached. In patients with diffuse lymphomas, histiocytic or lymphocytic, there was a very high rate of relapse in the first few years following either local or extended field irradiation. However, actuarial survival curves suggest that perhaps half of the small group of stage I and I<sub>E</sub> patients with diffuse disease may have been cured. In general, the configuration of the curves for patients with diffuse disease was similar to those seen in HD; the probability of relapse decreased very markedly with each succeeding disease-free year. Conversely, in patients with nodular disease there was little evidence for a reduction in the probability of relapse as the disease-free interval lengthened.

Comparable disease-free intervals have also followed chemotherapy<sup>112a</sup> or minimal radiotherapy and chemotherapy, and have occurred spontaneously.<sup>41,103a</sup> The entire concept of cure is made quite complex by the difficulty of distinguishing pathologically between benign lesions and well-differentiated NHL (page 1585). Most instances of localized, apparently cured disease involved such well-differentiated tumors that the "cured" disease may not have been lymphoma.<sup>50,105</sup>

### Palliative Therapy

If the patient is first seen when the disease is too extensive to consider "curative" therapy (page 1581), a period of observation may be advisable. Important considerations are the presence or absence of symptoms related to NHL, as well as the possibility of imminent complications of serious import, such as spinal cord compression (Chapter 54), and the degree of concern exhibited by the patient. The last factor is subject to considerable variation and is greatly influenced by the attitude of the physician and by his ability to convey to the patient a reasoned approach to the disease (Chapter 55). The advantage of a period of watchful waiting in patients who have relatively asymptomatic disease at the outset is that an opportunity is afforded

to assess the rapidity with which the disease is likely to progress without treatment. If rapid progression is observed, vigorous therapy may be in order, while, if little progression occurs, continued observation is justified. An example of the latter follows.

A 55 year old man was admitted to the hospital complaining of an enlarged cervical node, but he was otherwise asymptomatic. Biopsy of an enlarged node disclosed well-differentiated lymphocytic lymphoma, and bone marrow biopsy disclosed poorly organized nodules of lymphocytic infiltration. However, because the patient had no symptoms other than the enlarged node and his blood values were normal, no therapy was given. He chose to ignore the condition until six years after the diagnosis had been made, when he returned to "see how things were going." He was still healthy, still had palpably enlarged cervical nodes, and still had focal evidence of lymphoma on marrow biopsy even though his blood cell counts gave normal values.

In general it can be stated that follicular and lymphocytic lymphoma are more sensitive to therapy than is histiocytic. However, since individual patient response varies considerably, this general statement is of little use in specific instances. It has been said that bone marrow toxicity is no greater in NHL than in Hodgkin's disease with comparable doses of chemotherapeutic agents,<sup>81</sup> but our experience suggests that patients with NHL, particularly the lymphocytic forms, more easily develop pancytopenia during therapy. Thus, it seems reasonable to begin therapy with any marrow depressive agent at a lower dose in NHL than in HD until some assessment of tolerance has been obtained by observing the effects of the lower doses.

Palliative therapy (Chapter 55) is designed to reduce symptoms and to prolong comfortable life as well as to prolong life in the aggregate, if possible. Although unequivocal data from series of patients cannot be marshalled to provide evidence of prolongation of life as a result of therapy, there is little doubt that productive life has been increased in selected patients. When masses of lympho-

matous tissue produce local symptoms, their reduction by therapy decreases morbidity. Therapy of such complications as autoimmune hemolytic anemia can produce dramatic symptomatic relief (Chapter 54). Palliative therapy can be accomplished with x-irradiation<sup>107a</sup> or with chemotherapy. Combination chemotherapy, so useful in Hodgkin's disease (Chapter 50), has been employed in NHL, and has induced complete remission more often than when therapy with a single agent was given. However, the duration of response often has been short.<sup>84,85</sup> The frequency of complete remission following combined vincristine and prednisone appeared to be as high as when cyclophosphamide<sup>65,85</sup> or cyclophosphamide and procarbazine<sup>84</sup> were added to this combination. However, unmaintained remission may possibly be longer when vincristine, prednisone, cyclophosphamide, and procarbazine are used together<sup>84</sup> than when combinations of three or two drugs are used. It has been claimed that maintaining remission with various drugs may prolong the duration of remission in LLSa, but not necessarily in RCSa.<sup>85</sup> However, proof that maintenance therapy represents an advantage over reinduction of remission is lacking. Duration of survival of patients treated with combination chemotherapy was longer than in a group previously treated with sequential single-agent therapy,<sup>85</sup> but this was not a randomized comparison.

**THERAPY OF LEUKEMIC CONVERSION OF NHL.** If the conversion is to an ALL-like picture then the patient should be treated with the drugs used to induce and maintain remission in ALL (Chapter 47). Response to therapy may be as good in children developing ALL after a lymphosarcoma phase as in those having ALL initially,<sup>74</sup> but this has not always been true.<sup>5,128</sup> In general, the frequency of remission and the duration of remissions have been less in LSCL than in ALL.<sup>114,117</sup> Response to therapy of other forms of LSCL with alkylating agents has been disappointing in most cases.<sup>114,117</sup> Conversion to CLL should be approached in the

same manner as CLL (Chapter 49). Conversion to monocytic-histiocytic-reticuloendothelial cell leukemia is so infrequent that no useful therapeutic guidelines are available.

## Less Common Varieties of Non-Hodgkin's Lymphoma

Tissues other than lymph nodes may be the apparent primary site of origin of NHL, and since the clinical course of certain forms of *extranodal disease* may differ from that of disease beginning in lymph nodes, the extranodal type is discussed separately.

Lymphomatous tumors beginning in the skin will be discussed below in conjunction with two possibly distinct diseases, *mycosis fungoides* and *Sézary's syndrome* (page 1586). *Burkitt's (African) lymphoma* also is discussed separately (page 1590). Certain of the immunoglobulin-secreting tumors, especially those associated with *heavy-chain disease*, discussed in Chapter 53, have great clinical similarity to the non-Hodgkin's lymphomas. As noted in Chapter 49, *aleukemic chronic lymphocytic leukemia* is considered to be a form of LLs. Primary RCSa of bone is quite difficult to distinguish from *Ewing's sarcoma* on either histologic or clinical grounds<sup>60</sup> and consequently many authors exclude primary RCSa of bone from consideration with other lymphomas.<sup>109</sup> Malignant "histiocytoses" are hard to fit into a consistent classification of hematologic neoplasms, but as they must be distinguished from the lymphomas they are discussed in this chapter (page 1592).

### Extranodal Non-Hodgkin's Lymphoma

Initial clinical evidence of disease invading tissues other than lymph nodes or bone marrow is more common in NHL than in Hodgkin's disease, the lymphoid leukemias, or myelomas. In one large series,<sup>15</sup> 21% of the patients had evidence of invasion of tissues other than lymph nodes or bone marrow when first seen, and, in another series,<sup>109</sup> 37% had similar manifestations. It is unusual for follicular lymphoma to begin in this manner, but both the lymphocytic and histiocytic

forms do so. Unlike NHL arising in lymph nodes, extranodal disease is often localized to a single site.<sup>83</sup> Perhaps because of the tendency to remain localized, certain forms of extranodal disease offer a better chance for curative therapy than does primary lymph node disease.

The structures of the head and neck appear to be the most common sites. The tonsils, adenoids, and paranasal sinuses are most frequently involved, but the orbit, eyelids, tongue, thyroid gland, and virtually any other structure may be affected.<sup>45,109</sup> In one study of 292 patients with NHL which involved Waldeyer's ring, the disease was thought to be limited to that structure in 20%.<sup>74</sup>

*The gastrointestinal tract*, usually the stomach or less commonly small bowel or colon, is the initial site of disease in approximately 4% of patients with NHL and most cases are lymphocytic.<sup>45,76,109</sup> Gastric lesions may be ulcerative, diffusely infiltrative, polypoid, or appear as hyperplastic rugae or as combinations of these (Fig. 51-8). Initial symptoms are variable and include nausea, vomiting, anorexia, and vague abdominal pain as well as the classic symptoms of peptic ulceration. Protein-losing enteropathy may be found (Chapter 54).

Of 65 patients who proved to have gastric lymphoma and in whom no other evidence of lymphoma was present prior to surgical exploration, in 77% the disease was limited to the stomach; in the remainder the regional nodes were also involved.<sup>76</sup> However, gastric involvement is not necessarily the primary disease. In another series<sup>57</sup> of 75 patients in whom symptoms led to a diagnosis of gastric LLs in 64 and RCSa in 11, only 25 had disease apparently limited to the stomach. In still another group of 64 patients with involvement of stomach or bowel, all but two had disease elsewhere in addition to gastrointestinal disease.<sup>75</sup>

Prolonged survival and, in some instances, apparent cure are common in patients with lymphoma limited to the stomach. Survival of those with LLs, or in the rare instances in those with GFLs, was superior to that of patients with RCSa.<sup>76</sup> Similarly, patients

Fig. 51-8. Extensive involvement of the stomach such as may be seen in lymphosarcoma or in colloid carcinoma of that organ. The lesser curvature as well as the lower fundus and the pyloric regions are notably affected.

with small, superficial lesions appeared to have a better prognosis than those with the more extensive disease.<sup>76</sup> Although no comparative studies have been recorded, the apparent cure rate has been about the same whether the lesion was treated by excision, excision followed by radiotherapy, or biopsy followed by radiotherapy.<sup>57,76,109</sup> Survival of 59% of patients for five years and 28% for 10 years has been observed.<sup>76</sup> However, recurrence of disease as long as nine years after excision has been recorded.<sup>57</sup> The difficulty encountered in trying to relate survival or "cure" to the type of therapy employed is illustrated by a patient who remained apparently disease free for 15 years following partial excision of a gastric lesion even though he had enlarged regional lymph nodes and had not received radiotherapy.<sup>57</sup> The enigma of the lack of evident relation of type of therapy to end result has led to the suggestion

that certain gastric lesions considered to be lymphomas really represent benign lymphoid hyperplasia due to unknown cause.<sup>1,12,54,70</sup> It has been proposed that all lesions of the gut not associated with regional node involvement are "benign."<sup>1</sup> In a retrospective survey of pathologic material without knowledge of clinical outcome, when "benign lymphoid hyperplasia" was distinguished from "gastric lymphoma" on the grounds that benign disease is associated with long-standing peptic ulceration, particularly with overhanging ulcer margins, and the presence of other inflammatory cells and "true" germinal centers or extensive fibrosis,<sup>54,70</sup> only one of 21 patients classed as having "benign" disease was found to have died of lymphoma, while four of 13 classed as having lymphoma had done so.<sup>54</sup> This difference is suggestive but not statistically significant. In another series none of 12 considered to have benign disease had died while 14 of 15 with disease designated as malignant did so.<sup>70</sup> It is not clear, however, that this survey was made in a "blind" fashion. Thus, whether the unpredictable prognosis in gastric NHL is due to misdiagnosis of lymphoma or to innate variation in tumor behavior requires further study. Similar confusion exists concerning the less common primary involvement of the small bowel.<sup>103,139</sup>

*Primary NHL of the spleen* is in no sense common,<sup>2,20,42a,45,109</sup> but it presents two diagnostic problems. First, as with gastric lymphoma, it is possible that certain apparently cured primary lymphomas of the spleen (especially GFLSa) may have represented benign disease. Such cases include those reported as "cures" of primary GFLSa of the spleen following splenectomy, with survival for as long as 27 years.<sup>42,44,63,64</sup> Of 11 patients thought to have primary lymphosarcoma of the spleen at the time of splenectomy performed two to six years after a large spleen had been detected, six subsequently developed indications of CLL. The other five were alive without evidence of disease from one to 12 years after splenectomy even though focal lymphocytic infiltration had been noted in the liver at splenectomy.<sup>123</sup> In

a series of five patients in whom the spleen had a prominent follicular structure compatible with GFLSa at the time of splenectomy there was no evidence of recurrent disease at one, five, six, 10, and 13 years, postsplenectomy, respectively, despite the presence of increased lymphocytes in the bone marrow in all of them and blood lymphocytosis in some at the time of splenectomy.<sup>64</sup> Especially difficult to distinguish from primary NHL of the spleen on standard clinical grounds is "tropical" splenomegaly (Chapter 45). In the tropical disease, response to therapy with the antimalarial, proguanil, is expected; IgM levels are high and lymphocyte blastic transformation is normal; in contrast, IgM is normal or low and phytohemagglutinin (PHA) response usually has been abnormal in those proving to have NHL.<sup>112</sup>

Secondly, splenectomy is performed in occasional patients because of pancytopenia or a Coombs'-positive hemolytic anemia and yet histologic examination of the spleen fails to reveal a clear diagnosis. The spleen may have excessive numbers of small lymphocytes, but the distortion of architecture is so minimal that a diagnosis of LLSa cannot be made. Many of these patients later develop lymphoma, usually LLSa.<sup>10,64</sup> Dacie et al<sup>10</sup> reported nine patients with splenomegaly, all of whom were anemic and most of whom were neutropenic and thrombocytopenic but in whom no diagnosis could be made at the time of splenectomy. A diagnosis of LLSa was made in two of these patients, eight months and four years, respectively, after splenectomy; another died of unknown causes; six remained well with no diagnosis, two to seven years after splenectomy. Autoimmune hemolytic anemia has preceded the evident onset of RCSa by as long as seven years.<sup>38</sup> Whether in such cases lymphoma is present at the time of splenectomy but is unrecognizable by pathologic techniques, or whether the autoimmune phenomena precede and/or predispose to the development of lymphoma cannot be determined at present.

The diagnosis of lymphoma was made by diagnostic splenectomy in fewer than 1% of patients with lymphoma seen at the Mayo

Clinic<sup>2</sup> and in a series reported from India.<sup>45</sup> Of the 49 patients from the Mayo Clinic,<sup>2</sup> lymphoma was detected in abdominal lymph nodes or liver, as well as the spleen, in all but eight.

Primary NHL of bone most often is RCSa<sup>45,109</sup> although a variety of different histologic types may be encountered.<sup>69</sup> In view of the clinical differences between primary and secondary RCSa of bone and the histologic and clinical similarity of primary RCSa of bone to Ewing's sarcoma,<sup>50,109</sup> the "primary" condition may represent a different type of disease than other forms of NHL.

A variety of other sites have been noted as apparent primary sites of NHL, including skin, prostate gland, breast, kidney, bladder, ovary, testis, spinal cord, and various soft tissues.<sup>45,109</sup> In most cases, fatal dissemination has followed, although "cures" after excision or radiotherapy have occasionally been reported. Approximately 100 cases of NHL presenting as solitary pulmonary lesions have been reported. Such lesions may grow quite slowly, even if untreated.<sup>41</sup> However, the prognosis of seemingly localized extranodal NHL is not always better than that of nodal NHL; for instance, primary testicular disease has almost invariably been followed by generalized disease no matter what form of therapy has been employed.<sup>130</sup>

### Lymphomatous Tumors Beginning in the Skin

Any type of malignant lymphoma or leukemia may involve the skin as a manifestation of systemic spread of disease (Chapter 54) and, occasionally, NHL and Hodgkin's disease may begin as apparent primary tumors of the skin. In such instances, progression to a picture of generalized lymphoma usually, but not invariably, is observed.<sup>78</sup> There are, however, two primary tumors of skin, mycosis fungoides and the Sézary syndrome, that may be distinct from other lymphomas, although they may progress to diseases resembling systemic lymphoma and leukemia.<sup>19,51,105</sup> The term "mycosis fungoides" is an unfortunate one in that the disease is

not due to a fungus, as the name would imply. Furthermore, the term is not applied uniformly; some restrict its use to tumors with the "classic" histologic and clinical picture described below, while others apply it to any lymphomatous or leukemic process that begins in skin primarily.<sup>19,51,105</sup>

### **Mycosis Fungoides**

Mycosis fungoides may begin as a disease clinically and pathologically indistinguishable from psoriasis, seborrheic dermatitis, eczema, nonspecific exfoliative dermatitis, contact dermatitis, or neurodermatitis.<sup>18,51,105</sup> Pathologic distinction from these diseases becomes possible when the "indurative" or "plaque-forming" stage of the lesion develops. This, in turn, is followed by a "tumor-forming" stage.<sup>3,105</sup> The nonspecific skin eruption of the "premycotic" stage may persist for decades before the plaque-forming or tumor-forming stage is reached. In the largest series reported to date, the premycotic stage was present for a mean of four years.<sup>51</sup> Such a stage is not present in some patients; others seemingly go directly from the premycotic to the tumor-forming stage without an intervening stage of plaque formation.<sup>18</sup> Although rare in children, mycosis fungoides can occur in persons of any age and is slightly more common in males than in females.<sup>18,51</sup> The cells involved in the skin infiltrate may be histiocytes or plasma cells predominantly, or the cellular infiltration may be mixed and may include neutrophils and lymphocytes.<sup>3,105</sup> Epidermal changes are found in what is termed "mycosis fungoides,"<sup>45</sup> whereas primary skin involvement with lymphosarcoma or Hodgkin's disease usually does not include the epidermis. The epidermal changes consist of acanthosis, parakeratosis, elongated rete pegs, and spongiosis, in addition to "Darier-Pautrier abscesses," the intradermal clusters of histiocytes that often represent the first pathologic evidence of the presence of mycosis fungoides.<sup>105</sup> The indurative stage is characterized by cellular infiltration involving most of the upper dermis. As the tumor-forming stage is reached,

the infiltrate extends into the subcutaneous tissue.

The clinical appearance of the lesions parallels the pathologic evolution. A psoriatic-like plaque may be retained during the indurative stage and, as the tumor-forming stage is reached, the lesion becomes much more irregular. At all stages the skin feels indurated and firm. The absence of malignant characteristics in the cellular infiltrate in certain patients has led some to question the inclusion of mycosis fungoides with malignant neoplasms.<sup>3,105</sup>

At the time when a biopsy diagnosis is established, skin lesions clinically suggesting the premycotic stage are still found in approximately half the patients (Table 51-8). In one third, the tumor-forming stage has been reached by the time of diagnosis and, in these patients, ulceration and enlarged lymph nodes are fairly common (Table 51-8).

Anemia may be present and neutrophilic leukocytosis is frequent and appears to be correlated with the degree of skin infection.<sup>18</sup> Lymphocytosis may be detected, in which case some would consider the correct diagnosis to be Sézary's syndrome (see below). Eosinophilia may be noted. The bone marrow rarely is infiltrated but may contain increased plasma cells, perhaps due to the presence of chronic infection.

The tumor may be quite indolent; survival for many years is possible. Median survival from biopsy diagnosis in one series was four years and, when deaths apparently unrelated

**Table 51-8. Type of Skin Lesion and Frequency of Enlarged Nodes at the Time of Biopsy Diagnosis of Mycosis Fungoides (144 Patients)\***

	Percent of Patients
Skin tumors	33
Ulcerated tumors	13
Skin ulcers	15
Ulcers without skin tumors	2
Enlarged lymph nodes	28
No skin tumors, ulcers, or nodes	51

Fig 51-9 Survival from time of biopsy diagnosis of 144 patients with mycosis fungoides. Survival of all patients (lowest curve) those dying from mycosis (middle curve) and the expected age adjusted survival for the general population (upper curve) (From Epstein et al,<sup>51</sup> courtesy of the authors and Williams & Wilkins Company)

to mycosis fungoides were excluded, a "disease-oriented" median survival of five years was observed (Fig. 51-9).<sup>51</sup> A number of factors were found to influence survival.<sup>51</sup> Elderly patients survived a shorter time than those under the age of 50, even when non-tumor-related deaths were excluded. The presence of lymphadenopathy, skin tumors, and ulceration has prognostic significance (Fig. 51-10). When none of these was present, a median survival of eight years was observed, which declined to four years if one of these was present and to three years when two were present. A lymph node biopsy that discloses lymphoma is a poor prognostic sign as compared to one that does not provide a diagnosis. Duration of survival is quite short if hepatomegaly or splenomegaly is present.

Fig 51-10 The influence of the presence or absence of cutaneous tumors, ulcers, or enlarged lymph nodes on survival in patients with mycosis fungoides. None of these abnormalities was present at the time of diagnosis in the patients shown in the upper curve, one of the three was present in those represented in the middle curve, and two or all three findings were present in those shown in the lowest curve (From Epstein et al,<sup>51</sup> courtesy of the authors and Williams & Wilkins Company)

Sex, race, and the duration of the premalignant stage had no prognostic implications.<sup>51</sup>

The majority of patients develop evidence of systemic lymphoma by the time of death<sup>51</sup>; however, in certain small series, systemic lymphoma developed only in a minority.<sup>3</sup> Biopsy of enlarged lymph nodes during life more commonly demonstrates reactive hyperplasia than lymphoma.<sup>3,51,105</sup> The type of lymphoma reported has been quite variable.<sup>3,18,51,105</sup> Hodgkin's disease, LLs, RCLs, and mixed lymphomas with cellular infiltration similar to that seen in the skin have been reported. The development of different cytologic types of lymphoma in the course of mycosis fungoides is one of the factors that has led some to suggest that mycosis fungoides is not a disease, per se, but rather a manifestation of any type of lymphoma beginning in the skin.<sup>107</sup>

Infection is the cause of death in most patients; this is usually spread terminally from chronically infected, ulcerative skin lesions.<sup>51</sup> As with other lymphomas, general debilitation and widespread disease may be present without an identifiable specific cause of death.<sup>51</sup>

### Sézary's Syndrome (Erythrodermia)

Sézary<sup>121</sup> described a series of patients<sup>120</sup> with a syndrome characterized by intensely pruritic generalized erythrodermia, atypical lymphocytic cells<sup>39</sup> in the blood, and cutaneous infiltration with atypical lymphocytes and histiocytes. Lymphadenopathy and hepatosplenomegaly often were present. The disease is rare, a total of about 30 to 40 patients having been reported in the medical literature.<sup>88,132</sup> Prolonged survival is the rule, patients living an average of approximately five years from onset of symptoms.<sup>26</sup> An identical clinical picture can be observed in patients with a CLL-like disease (Fig. 51-11), in those who initially have lymphocytic skin infiltration and eventually develop CLL, or in patients in whom the findings on skin biopsy are interpreted as indicative of mycosis fungoides.<sup>51</sup> Thus, to distinguish this syndrome from CLL and mycosis fungoides,

**Fig 51-11** Leukemia cutis universalis. The clinical examination of this patient revealed findings very similar to those designated as the Sézary syndrome, yet examination of his blood suggested a diagnosis of chronic lymphocytic leukemia. There was desquamation of the skin of the whole body and most of the hair was gone. The skin of the face, forehead and ears was swollen and the eyelids were infiltrated. The leukocyte count was  $30 \times 10^9/l$ , of which 73% were lymphocytes. All the accessible lymph nodes were greatly enlarged. On section, the cutis was found to be densely infiltrated with lymphocytes. The patient died of lobular pneumonia. None of the lymph nodes in the interior of the body was enlarged. The spleen was not increased in size, and there was only slight periportal infiltration of lymphocytes in the liver.

it is necessary to identify the "characteristic" blood cell or cellular infiltration of the skin. In one patient with Sézary's syndrome, the lymphocytes responded to PHA and showed chromosome abnormalities,<sup>39</sup> unlike the lymphocytes in CLL (Chapter 49). The similarity of appearance on electromicroscopy of "Sézary cells" and the cells infiltrating the skin in mycosis fungoides has led to the suggestion that the Sézary syndrome may be the leukemic phase of mycosis fungoides.<sup>88</sup>

The cells in the blood usually are numer-

ous enough to produce leukocytosis. They are rather large, 15 to 25  $\mu$ m in diameter, with irregular cytoplasmic borders in stained, fixed blood smears. The cytoplasm is light to dark blue and is fairly abundant. The cells often stain intensely with PAS (page 29), presumably reflecting a high glycogen content. However, intense staining of lymphocytes with PAS also may be observed in CLL and in LSA or in nonmalignant diseases such as infectious mononucleosis.<sup>93</sup> The suggestion that the Sézary cell could be distinguished by diastase-resistant PAS positivity<sup>131</sup> was not confirmed.<sup>31</sup> The nuclei are oval or round or may have clefts, and the nuclear chromatin is densely clumped. Nucleoli usually are not apparent in Wright-stained smears. The membrane characteristics of Sézary cells are those of "T" lymphocytes,<sup>26a,146</sup> while the cells in most lymphomas and CLL have the characteristics of "B" lymphocytes (Chapter 46). That these cells can be distinguished morphologically from the atypical lymphocytes seen in the blood of some patients with otherwise clinically typical CLL (Chapter 49) or lymphosarcoma invading the blood (page 1579) has not been demonstrated in a controlled study.

Pruritus almost always is the initial complaint. The skin appears red and is diffusely thickened. Demarcation between involved and uninvolved areas is poorly defined. The infiltration may involve the entire skin and in its extreme form often results in extensive exfoliation (Fig. 51-11). Edema of patchy nature often is a feature, and hyperpigmentation develops commonly. Body hair is lost and, with scalp involvement, total alopecia may develop. Hyperkeratosis of the palms of the hands and soles of the feet is common and fingernails and toenails become dystrophic and may be lost as nail beds are affected.

The disease may remain localized to the skin for some years but, in most subjects, lymphadenopathy and hepatosplenomegaly occur eventually. The cells infiltrating lymph nodes and other organs are similar to the cells in the blood.

### Therapy of Mycosis Fungoides<sup>51,91,136</sup> and Sézary's Syndrome<sup>30,34</sup>

Systemic chemotherapy may have a prolonged palliative effect, corresponding to what is expected with other forms of lymphoma (page 1581). Alkylating agents, such as chlorambucil and cyclophosphamide, HN2, and BCNU, and antimetabolites, such as methotrexate, often are beneficial.<sup>51</sup> Prednisone may produce dramatic effects in erythrodermia and in other forms of skin involvement with lymphocytic cells, but often is less effective in "classic" mycosis fungoides. Azaribine, a purine analog, has been claimed to be one of the most effective of the therapeutic agents.<sup>91</sup>

Irradiation of the skin with rays of low penetrance, such as electron beams, often is helpful, but the machines delivering such rays are available only in a few specialized treatment centers.<sup>51</sup> Periodic application of 10 to 40 mg of nitrogen mustard, dissolved in 30 to 60 ml of tap water, to the entire skin surface has been found useful in patients with the diffuse type of skin lesions but has not been as effective when discrete tumors were present.<sup>136</sup> General application of 10 mg HN2 (dissolved in 60 ml of water) to all of the skin two to three times each week, coupled with local injection of nodular lesions, led to complete remission, often of long duration, in 50% of 75 patients so treated.<sup>136a</sup> Although hypersensitivity to HN2 was a frequent complication, desensitization with small, intravenous doses proved feasible. The completeness of the response to the first course of therapy bears little, if any, relationship to duration of survival.<sup>51</sup> Therapy, although palliative, may not prolong life.

### Burkitt's Lymphoma (African Lymphoma)

A form of sarcoma that is predominantly extranodal and has a special and unique predilection for the jaw and facial bones was described in natives of Uganda by Burkitt.<sup>1,28</sup> The disease is common in certain parts of Africa and New Guinea, but is rare in other

portions of the world. As discussed in Chapter 46, the evidence for an etiologic relation of Burkitt's lymphoma to a virus is perhaps stronger than for any other form of leukemia or lymphoma. The relatively recent recognition of this tumor probably reflects the lack of consistent medical care in most parts of Africa, rather than the development of a new disease; the clinical syndrome apparently was known many years ago.<sup>99</sup>

The tumor usually, but not exclusively, is found in children.<sup>99,145</sup> Males are affected slightly more often than females. The tumor is extranodal in most patients at the time of diagnosis, but lymph nodes, liver, and spleen may be involved when the diagnosis is made or at autopsy. In the majority of patients, more than one site is affected at the time of diagnosis. When the tumor is confined to a single site, it most often is found in the facial bones, especially in the mandible and maxilla (Fig. 51-12). Abdominal and pelvic viscera, retroperitoneal soft tissues, salivary glands, thyroid gland, long bones, and the central nervous system are sites involved with some frequency. Unlike other types of NHL in children, leukemic conversion is rare, at least in Africa.<sup>37</sup> Approximately 16% of these patients develop tumor in marrow, but even in these the blood usually is spared.<sup>21</sup>

The tumor consists primarily of large, immature lymphoid cells interspersed with isolated large macrophages, thereby producing its characteristic "starry-sky" histologic appearance (Fig. 51-13).

Burkitt's tumor is remarkably sensitive to chemotherapy with cyclophosphamide or methotrexate.<sup>102</sup> More than half the patients have achieved a complete remission after a single dose of cyclophosphamide, 40 mg/kg,<sup>33</sup> and approximately 20 to 50% were apparently cured by this method.<sup>29,36,140</sup> Patients who fail to achieve remission with a single dose usually do so after repeated doses. Long-term, disease-free interval following therapy is more common if the disease is localized rather than disseminated, but dissemination does not preclude a good prognosis.<sup>138a</sup> The same percentage of patients achieving re-

Fig 51-12 Burkitt's lymphoma involving mandible, maxilla and orbit (From O Conor,<sup>99</sup> courtesy of the author and Cancer Research)

mission and long-term survival was observed when remission was induced with six doses of cyclophosphamide as when induced with combination chemotherapy employing cyclophosphamide, vincristine, methotrexate, and cytosine arabinoside.<sup>144</sup> In a study in which various forms of therapy were used, 80% of 130 patients eventually achieved remission.<sup>145</sup> Spontaneous remission also may occur.<sup>30</sup>

A tumor with apparently identical morphologic appearance is seen occasionally in American children<sup>33,49,101</sup> or in children in other countries such as Colombia<sup>10</sup> or India.<sup>45</sup> In these children, abdominal tumors are more common, tumor of the facial bones is less common, and bone marrow involvement is more frequent than in African children. African children with the tumor tend to have increased serum IgG levels and decreased IgM, whereas in American children IgG has been normal or decreased and IgM

Fig 51.13 Histologic appearance of Burkitt's lymphoma. There is a uniform infiltration with immature lymphocytes, among which histiocytes are interspersed giving the so-called "starry-sky" appearance (Magnification  $\times 400$  and  $\times 1000$ , respectively) (From O'Connor,<sup>100</sup> courtesy of the author and American Journal of Medicine)

normal. A small group of American children have experienced prolonged remissions following cyclophosphamide therapy similar to those observed in Africa. Whether the non-African disease is the same as or different from the African variety must await further study

### Reticuloendothelioses

In 1923, Ewald<sup>12</sup> described a disease that he termed "leukemic reticuloendotheliosis." The two characteristics that he considered

distinctive were a very large spleen and increased mononuclear cells with numerous cytoplasmic projections in stained smears of blood. A variety of reports of diseases that bear some similarity to that described by Ewald have appeared under titles such as "histiocytic medullary reticulosis,"<sup>117a</sup> "familial haemophagic reticulosis,"<sup>55</sup> "reticulosis,"<sup>55</sup> "aleukemic reticuloendotheliosis,"<sup>58</sup> "reticuloendotheliosis,"<sup>96</sup> "lymphoreticular neoplastic disease,"<sup>115</sup> "reticulum cell leukemia,"<sup>81,132</sup> "chronic reticulolymphocytic leukemia,"<sup>110,131</sup> and still other terms.<sup>105</sup> These

are thought to be neoplastic diseases of the reticuloendothelial system. Their identification as distinct syndromes is as difficult as defining the reticuloendothelial system (Chapter 8). The relationship of some of them to acute or chronic monocytic leukemia (Chapters 47 and 48) or to RCSa or leukemic conversion of NHL is uncertain.

From information in the literature and from limited personal experience with such patients, for they are rare, it seems justifiable to recognize certain reticuloendothelioses as malignant, neoplastic diseases that can be separated from other forms of leukemia or lymphoma on the basis of histologic findings and perhaps on clinical grounds. Most case reports, no matter what term was employed by the authors, would appear to fit one of the following described syndromes: leukemic or aleukemic reticuloendotheliosis, histiocytic medullary reticulosis, and familial haemophagic reticulosis. Furthermore all of these have certain features in common and whether they are different diseases or variants of the same disease cannot be determined at present.

#### Leukemic and Aleukemic Reticuloendotheliosis

The clinical features<sup>4,31,55,58,110,115,133,135,142</sup> can be summarized as follows. Most patients are elderly, although persons of virtually any age may be affected; males are more commonly affected than females. Presenting complaints are fatigue, malaise, infection, and/or abdominal discomfort. The spleen is enlarged in most patients, often filling the left side of the abdomen. Hepatomegaly is common and lymphadenopathy often has been described although the nodes have been small in most patients. Fever, without evident infection, is common. Mild to moderate anemia is detected in most patients, as is moderate to severe thrombocytopenia. Neutropenia often is present but the total leukocyte count is low, normal, or elevated, depending upon the number of abnormal mononuclear cells in the blood. If significant numbers of abnormal cells are found in the blood, the disease is said to

be "leukemic," if absent, "aleukemic," but other differences between such patients are not apparent.<sup>58</sup> Eosinophilia may occur.<sup>82</sup> Marrow aspiration may reveal the abnormal-appearing cells or a "dry tap" may be obtained, in which instance the marrow biopsy may disclose a hypoplastic parenchyma with the abnormal cells present in moderate numbers.

The diagnosis depends on the histologic appearance of the infiltration, whether in blood, spleen, marrow, or lymph nodes. In sections of tissue, the infiltration is distinguished from the histiocytic infiltration in certain forms of lymphoma by being diffuse in nature rather than occurring in nodular aggregates. Furthermore, if spleen or lymph node cells are examined in a living state after having been teased free from tissue, they show the characteristic flagellated appearance that characterizes the cells described in the blood.<sup>115,133</sup>

The abnormal cells in the blood have been referred to as "hairy" cells because of the irregular cytoplasmic villi that give the cell a flagellated appearance in stained (Fig. 51-14A), living (Fig. 51-14B), or electron microscopic preparations.<sup>115,133,142</sup> The cell is large, usually 15 to 30  $\mu$ m in diameter, with a round or oval nucleus and fairly abundant gray-blue cytoplasm. The nuclear chromatin is moderately clumped and nucleoli usually are not visible or are small. Because its cell line of origin is unclear,<sup>115,133</sup> such terms as "chronic reticulolymphocytic leukemia"<sup>110</sup> have been used. Histochemical and cellular function studies suggest that the "hairy" cell shares certain characteristics common to both lymphocytes and monocytes. Acid phosphatase activity in the cells of patients with leukemic reticuloendotheliosis is prominent and is resistant to degradation by tartrate, whereas the cells in those with CLL or LSA have minimal activity and this is degraded by tartrate.<sup>143</sup> Other studies have suggested that the cell is lymphocytic.<sup>31a</sup>

The disease characteristically follows a rapid course with death usually occurring within four to six months after the diagnosis has been made. No form of therapy is of

Fig 51-14 "Hairy" cells from an imprint of spleen (A) and from a buffy coat preparation (B) from a patient with leukemic reticuloendotheliosis. (From Trubowitz et al.<sup>133</sup> courtesy of the authors and Grune & Stratton.)

predictable benefit, although splenectomy has been reported to lead to improvement in some patients.<sup>33a</sup>

### Histiocytic Medullary Reticulosis

Histiocytic medullary reticulosis was first described in 1939 by Scott and Robb-Smith.<sup>117a</sup> From clinical<sup>88</sup> and pathologic<sup>89</sup> study it is difficult to distinguish this syndrome from "aleukemic reticuloendotheliosis"<sup>58</sup> except for two features, namely, (1) prominent erythrophagocytosis by histiocytes

and (2) anemia due, at least in part, to a hemolytic process. The hemolysis is thought to be due to erythrophagocytosis by the histiocytes.<sup>97</sup> More than 50 cases have been reported,<sup>34</sup> but some of these patients have not exhibited erythrophagocytosis and how such cases differ from cases of "aleukemic reticuloendotheliosis" is uncertain.<sup>58</sup> The clinical features of histiocytic medullary reticulosis<sup>34,39,88,120</sup> are those described above for reticuloendotheliosis. The initial symptoms are fever, fatigue, weight loss, and/or an abdominal mass. The physical findings

consist of splenomegaly, often with hepatomegaly and lymphadenopathy, and, most commonly, pancytopenia. Fatal hemorrhage associated with thrombocytopenia and evidence for massive platelet phagocytosis by histiocytes has been reported.<sup>118</sup> A histiocytic leukemic phase has not been described, but a blood picture resembling ALL (Chapter 47) has been found at the initial examination.<sup>34</sup> Inclusions in erythrophagocytic histiocytes have been thought to resemble the cells seen in Niemann-Pick disease (Chapter 42), but the lipid profile was not compatible with the latter disease.<sup>138</sup> The course is rapid, survival for more than six months being unusual, but a few patients have improved after splenic irradiation or splenectomy,<sup>115</sup> or with steroid therapy.<sup>34</sup>

*Familial hemophagic reticulosis*<sup>9,55</sup> apparently is indistinguishable from histiocytic medullary reticulosis except for its familial occurrence. Four infant siblings were affected in one family in which both parents were healthy.<sup>55</sup> Consequently, the disease may represent an autosomal recessive genetic defect.

The reliability of the single factor, presence or absence of erythrophagocytosis by histiocytes, as a means of distinguishing between two forms of a disease can be questioned. Phagocytic capacity often is considered a function acquired by such cells as they mature (Chapters 6 and 45). It seems possible that all of the "reticuloses" represent one basic disease and that histiocytic medullary reticulosis represents a more differentiated form of disease than aleukemic or leukemic reticuloendotheliosis. In addition to differentiation from other leukemias and lymphomas, these reticuloendothelioses must be distinguished from other idiopathic diseases characterized by excessive numbers of histiocytes in the tissues. The clinical manifestations of histiocytosis-X (eosinophilic granuloma, Hand-Schüller-Christian disease, and Letterer-Siwe's disease) (Chapter 42) differ from those of the "reticuloses" and, in addition, in histiocytosis-X the histiocytes stain with Gomori's silver-impregnation method, while those of the reticuloendothelioses do not.<sup>48</sup>

*Multicentric reticulohistiocytosis*, while similar in title to the malignant reticuloendothelioses, is a crippling, but not fatal, disease associated with histiocytic infiltration of joints and skin that produces chronic deforming arthritis.<sup>8</sup>

## General Considerations

### Definition

The plasma cell and lymphocyte dyscrasias include a number of disorders that share two basic characteristics: (1) the seemingly uncontrolled proliferation of cells normally involved in antibody production; and (2) the synthesis and secretion by these cells of a structurally homogeneous gamma globulin ("M-component") and/or its constituent polypeptide subunits. The structure of these proteins and the function of their "normal" immunoglobulin counterparts were discussed in Chapter 7.

These dyscrasias include (1) multiple myeloma, which is the most common; (2) Waldenström's macroglobulinemia; (3) the

heavy chain diseases; (4) "benign" monoclonal hypergammaglobulinemia; (5) certain forms of "essential" monoclonal cryoglobulinemia; and, probably, (6) amyloidosis. On the basis of morphologic and clinical criteria, Waldenström's macroglobulinemia and heavy chain disease are more properly identified as lymphocyte dyscrasias, whereas the others are plasma cell dyscrasias, but the latter term is usually used in referring to all these disorders.

### History

The early development of our knowledge of multiple myeloma<sup>40,83,141,261</sup> was described in an earlier chapter (page 1433). Since then the fundamental studies of Grabar, Heremans, Waldenström, Osserman, Putnam, Edelman, Franklin, and others have further delineated the clinical, pathologic, and immunochemical characteristics of these diseases (see below).

### Etiology

Some of the more general aspects of the pathogenesis and etiology of the neoplastic diseases of the hematopoietic system were discussed in Chapter 46. Here the plasma cell dyscrasias will be considered more specifically.

The exact cause of plasma cell dyscrasias remains obscure, but possible clues have

come from experimental studies in animals<sup>187</sup> and from certain clinical observations in man. The importance of *genetic factors* is suggested by the observation that spontaneously occurring plasma cell dyscrasias in mice,<sup>200,201</sup> those occurring in association with cecal ulceration,<sup>63,182,191</sup> and those induced by mineral-oil injection and similar means<sup>185,188,190</sup> are confined to specific strains of mice. In man a role for genetic factors is suggested by reports of plasma and lymphocyte dyscrasias occurring in siblings and other near relatives.<sup>4,15,33a,97,162</sup>

*Chronic stimulation of the reticuloendothelial system* also may be an important factor in the development of plasma cell dyscrasias. Thus the development of plasma cell tumors in anatomic proximity to chronic cecal irritation in C3H mice<sup>63,182</sup> and the development of myeloma following injection of Freund's adjuvants, mineral oil, and plastics in BALB/c mice<sup>185,188,190</sup> have been quoted in support of this view. In man, plasma cell dyscrasias of all types have been found in conditions associated with chronic RES stimulation, such as chronic osteomyelitis, pyelonephritis, tuberculosis, and chronic hepatitis.<sup>173</sup> The association between chronic infection and amyloidosis also is well known.<sup>174</sup> In addition, the association of human plasma cell and lymphocyte dyscrasias with rheumatoid arthritis,<sup>80,256,268</sup> Sjogren's syndrome,<sup>265</sup> and other autoimmune diseases is noteworthy. It is possible, of course, that a third independent factor may be responsible for both sets of clinical manifestations.

More recently, *viruses* have been suspected as etiologic agents in plasma cell dyscrasias. Thus, Aleutian mink disease, which is caused by a transmissible viral agent, is characterized by various manifestations of chronic viral infections such as lymphoreticular hyperplasia, autoimmune phenomena, and hypergammaglobulinemia.<sup>183</sup> About 10% of the infected animals also develop a monoclonal gamma globulin pattern and some excrete Bence Jones protein. Again, in mice, intracisternal A particles have been found in every plasmacytoma so far examined by electron microscopy<sup>54</sup> and, while it has been

claimed that these particles may simply represent evidence for viral superinfection in immunologically debilitated hosts, it is equally possible that they represent defective tumor viruses. The association of an unusual type of RNA-dependent DNA polymerase enzyme with intracisternal A particles strengthens the latter argument.<sup>260</sup> Furthermore, in addition to A particles, two types of C-type particles have been described in association with mouse myeloma cells. One contains the antigens associated with MuLV (Gross) virus infection,<sup>112,255</sup> whereas the other is a new virion antigen, VEA,<sup>12</sup> which is found on the surface of some mouse plasmacytomas (BALB/c) but not others. It was also shown that normal BALB/c mice have natural antibodies against this antigen.<sup>90</sup> Finally, myeloma has been transmitted from man to immunoincompetent animal hosts by intact myeloma cells or unirradiated cell filtrates,<sup>158</sup> suggesting a role for a filtrable but viable agent in the transmission of myelomatosis.

### The Protein Abnormalities

Characteristic protein abnormalities are central features of plasma cell and lymphocyte dyscrasias. The homogeneity of these proteins has made them invaluable tools in the hands of immunochemists and is in large measure responsible for our understanding of normal immunoglobulin structure and function. In addition, these proteins are of considerable importance in the diagnosis of multiple myeloma and related disorders, and sometimes their special properties contribute directly or indirectly to the clinical manifestations of these diseases. It is therefore fitting that their structural and functional characteristics be considered before discussing the clinical manifestations of the various plasma cell dyscrasias. Readers unfamiliar with the nomenclature and structural properties of immunoglobulins are referred to Chapter 7 (pages 305 to 313); tests for the identification and measurement of specific normal or abnormal immunoglobulins are discussed on pages 337 to 339.

Increased concentrations of structurally homogeneous proteins, called "M" (Myeloma or Macroglobulinemia) components, are found in the serum and/or urine of most patients with plasma cell dyscrasias. Such M-components occur in three major patterns: (1) complete gamma globulin molecules which may be IgG, IgA, IgM, IgD, or IgE, and may contain either  $\kappa$  or  $\lambda$  light chains; (2) free  $\kappa$  or  $\lambda$  light chains, either alone or in addition to complete immunoglobulin molecules carrying the same light chain type; and (3) fragments of heavy chain only, generally without the concomitant production of free light chains. When examined by *electrophoretic techniques* (page 337) these proteins appear as tall, narrow, sharply defined peaks that reflect their structural homogeneity (Fig. 52-1). For diagnostic purposes these characteristic contours are of greater importance than the height of an individual spike, although the latter is a good index of the amount of protein present. Electrophoresis also indicates the relative mobility of a given protein ( $\alpha$ ,  $\beta$ ,  $\gamma$ ) as well as the distribution and concentration of the normal serum proteins. Thus IgG has  $\gamma$  mobility predominantly, IgA has  $\beta$  mobility, and IgM, IgD, and IgE have  $\gamma$  to  $\beta$  mobility (Chapter 7).

The structural identity of M-components is usually established by *immunoelectrophoretic techniques* (page 338). First, polyvalent antisera containing antibodies against all serum components are used (Fig. 52-1). In such a test, normal serum proteins are recognized by the characteristic patterns and positions of their arcs; M-components, while maintaining their appropriate electrophoretic position, appear as thickened arcs with smaller than usual radii. These characteristics reflect their greater structural homogeneity and compact pattern of mobility. In addition to complete M proteins, immunoelectrophoresis may also detect gamma globulin fragments; free light chains usually migrate with  $\gamma$  to  $\alpha_2$  mobility, whereas free heavy chain fragments are generally found in the  $\gamma$  or  $\beta$  regions. In contrast to plasma cell dyscrasias, conditions associated with diffuse hypergammaglobulinemia, such as chronic

infections, show thickened immun arcs that have maintained their no. tours (Fig. 52-1).

While immunoelectrophoresis w valent antisera usually is conclus laboratories prefer to establish the specificities of a given M-compone use of univalent antisera with spec one of the five identifiable H chau of the two known L chains. In addit ous techniques have been develo make it possible to determine the ex tity of a given protein in the serum (Chapter 7).

The presence of *light chains* in is best detected by electrophoretic te that typically reveal the presenc M-component, with  $\gamma$  to  $\alpha_2$  mobil concentration greater than that of The findings may be confirmed by i electrophoretic techniques using specific for  $\kappa$  or  $\lambda$  chains. Wheo ligl have the thermal properties of a *Be. protein*, their presence can also be o by precipitation at 50° to 60° C dissolving at 90° to 100° C. The reappears on cooling. The incidence tive reactions is maximal if the pE urine is carefully adjusted to 4.5 to ! times, but even under optimal cc some light chains do not give the teristic thermal pattern.

If the common form of proteinuria ent, confusion may arise since other will also precipitate at higher temp Such proteins must be filtered off af have coagulated at boiling and the Jones proteins are redissolved. The then repeated. Alternatively, the *tol. fonic acid (TSA) test*<sup>43</sup> can be used situations. In this test, 1 ml of TSA (12 g para-toluene sulfonic acid in s glacial acetic acid to make 100 ml) i to 2 ml of fresh urine by allowing the to run slowly down the side of the n tube is flicked with the finger and if t tion is positive, a precipitate will within 5 minutes. Albumin in concen up to 25 g/dl or  $\alpha$ ,  $\beta$ , and  $\gamma$  globulir 500 mg/dl will not interfere with th

The factors responsible for excessive production of intact M-proteins, the unbalanced production of constituent chains, and the synthesis of altered proteins are unknown. Under normal conditions, synthesis of heavy chains and that of light chains are approximately equal (Chapter 7), and if heavy and light chain synthesis remains balanced in the markedly expanded cell pool of a plasma cell dyscrasia, an intact homogeneous M-component will result. In certain other situations, light chains are produced in excess of heavy chains. This may be due to the proliferation of two separate clones of cells or to a defect in regulatory genes within a single cell line. In some instances, complementary heavy chain production is virtually undetectable ("light chain disease") and, in a few instances, synthesis of heavy and light chains ceases altogether, especially late in the disease (see also page 1613).

Myeloma proteins were at one time considered to be monoclonal "nonsense" proteins without functional significance. However, an ever-growing number of human<sup>25,78,155,269,270</sup> and murine M-components<sup>66,186,187,189,223</sup> with specific antibody activity are now recognized. Thus it is possible that at least some plasmacytomas originate from precursors engaged in natural immune responses and that the M-components of these plasma cell dyscrasias may represent abnormal concentrations of functional antibodies.

Structurally altered proteins and polypeptide chains have been noted with increasing frequency. The most striking examples are seen in patients with "heavy chain disease" that is characterized by M-components consisting of heavy chains with large internal deletions (page 1630). Smaller deletions of parts of the H and L chains have, however, also been demonstrated in apparently intact myeloma proteins. It seems likely that, in all of these instances, the abnormal protein is the result of a defect or mutation within a structural gene.

Some M-components contribute to the clinical manifestations of plasma cell and lymphocyte dyscrasias because of their spe-

cial physicochemical properties. These include (1) precipitation in the cold (cryoglobulins); (2) a high intrinsic viscosity; (3) the ability to complex with other serum proteins such as clotting factors; and (4) the amyloidogenic properties of some light chain fragments. These special properties of immunoglobulins and their fragments will be discussed in the appropriate clinical context. In addition, M-components may increase the catabolism of normal immunoglobulins, thereby leading to low levels of functional immunoglobulins (page 1606).

## Multiple Myeloma

### Definition

Multiple myeloma is a neoplasm of plasma cells, the clinical manifestations of which are dictated by the characteristic bony lesions produced by the tumor, the effects of marrow replacement by tumor tissue, and the pathologic manifestations occasioned by the overproduction of myeloma proteins and their constituent polypeptide chains.

### Incidence

The reported incidence of multiple myeloma has more than doubled during the past two decades,<sup>124,140,150,246</sup> most likely because of the wider use of protein electrophoresis and bone marrow aspiration in diagnosis.<sup>150</sup> Cases have been reported from all parts of the world and no race is known to be immune. In the United States the incidence in Negroes is at least twice that in Caucasians.<sup>140,150</sup> Reported incidence rates are about one to two per 100,000 population in whites and two to four per 100,000 population in blacks per year.<sup>150</sup> While myeloma may be diagnosed as early as the third decade of life the incidence increases with age and reaches a peak during the seventh decade.<sup>150</sup> The disease is probably somewhat more common in males than in females.<sup>176</sup>

## Clinical Manifestations

It is now well recognized that the clinically apparent stage of multiple myeloma is usually preceded by an asymptomatic period of variable duration<sup>90,123,241,253,265</sup> and a few instances of asymptomatic myeloma lasting for two decades have been reported.<sup>165</sup> During this time an elevated erythrocyte sedimentation rate, an M-component on serum electrophoresis, or unexplained proteinuria may be the only manifestations of the disease. As the illness progresses, recurrent infections, weakness, and weight loss become prominent features, to be followed by symptoms resulting from the presence of skeletal lesions and, ultimately, from the development of chronic renal disease.

Increased susceptibility to infection is a common initial finding and constitutes the major cause of death.<sup>258</sup> Myeloma patients characteristically suffer from repeated bouts of sepsis, usually due to high-grade encapsulated organisms such as pneumococci,<sup>83,230,271</sup> but infections due to gram-negative organisms are becoming increasingly prevalent.<sup>156</sup> Thus the patterns of sepsis in multiple myeloma<sup>71</sup> resemble those seen in children with sex-linked agammaglobulinemia (Chapter 44) and in patients with other hematologic neoplasms who have decreased serum levels of normal immunoglobulins (Chapters 44 and 54).

The increased susceptibility to infection is attributable to several factors, the most important of which are low levels of normal immunoglobulins due to (1) defective antibody synthesis,<sup>49,71,92,113,149,271</sup> and (2) an increased rate of gamma globulin catabolism<sup>135,232</sup> (Chapter 44). As a result, normal immunoglobulin levels are almost always decreased and are often less than 20% of normal.<sup>149</sup> These deficits involve all immunoglobulin classes, irrespective of the type of M-protein produced by the malignant cells. Susceptibility to bacterial sepsis is further increased by (3) the frequent occurrence of severe granulocytopenia that occasionally is due to marrow replacement by tumor cells

but, more commonly, is a result of cytotoxic chemotherapy. In addition, functional defects of granulocytes have been reported.<sup>180</sup> Cellular immunity (Chapter 7) is less severely affected, although a delayed rejection time of skin allografts<sup>131</sup> and defective *in vitro* responses of lymphocytes have been reported by some,<sup>93,215</sup> but not by others.<sup>98</sup> In keeping with these findings, myeloma patients are not particularly susceptible to viral infections, with the possible exception of localized and disseminated herpes zoster.<sup>157,170</sup>

The skeletal lesions come to light because of the discovery of a swelling or because of local tenderness, unrelenting pain, or a pathologic fracture. Myelomatous tumors characteristically are multiple and are mainly confined to the sites of red marrow: the ribs, sternum, spine, clavicles, skull, or the extremities about the shoulder or pelvic girdle. Proptosis is a common presenting sign when there is orbital involvement.<sup>207</sup> Palpable swellings generally range from the size of a pea to that of a hazelnut and are elastic and yielding. Parchment-like crepitations may sometimes be elicited. More commonly, however, the only evidence of tumor detected by physical examination is an area of bony tenderness.

Initially the pain is often "rheumatic," wandering, and intermittent and most commonly involves the back, less often the chest or extremities. Girdle sensation or radiation down the legs may be present. The pain may be very severe and may last for hours, days, or longer, but intermittency and even prolonged remissions are common.<sup>83</sup>

Pathologic fractures are frequent, but since they are usually confined to the trunk, they may not be recognized as such initially, but, instead, their manifestations may be considered to be due to pleurisy or neurologic disease. Thoracic deformity is a common end result of multiple fractures of the ribs and sternum, and height may be decreased by several inches because of recurrent compression fractures of thoracic and lumbar vertebrae.

Characteristic bone changes may be dem-

Fig. 52-2 Punched-out lesions in the skull of a patient with multiple myeloma

onstrated by roentgenograms which show rounded, punched-out areas (Figs. 52-2, 3, 4) in the sites already mentioned. Periosteal reactions and spontaneous new bone formation are rare,<sup>104</sup> but may occur with successful therapy.<sup>208</sup> In the ribs the osteolytic lesions frequently have the appearance of diffuse mottling, while in the spine they are evidenced by rarefaction, globular tumor formation, shortening and twisting of the vertebral column, and disappearance of intervertebral discs. Similar multiple, small, discrete, osteolytic lesions may be produced by metastatic carcinoma of the breast or thyroid gland or by other conditions.

In some patients, especially early in the disease, diffuse osteoporosis may be seen instead of discrete punched-out lesions, and in an increasing number of patients no bony lesions whatsoever are demonstrable at the time of diagnosis.<sup>95</sup> Nevertheless, when microradiographic rather than standard radiographic techniques are used, generalized thinning and destruction of trabeculae may be demonstrated.<sup>237</sup> Similar changes are noted in histologic studies. Most patients

without lytic changes on initial presentation eventually develop typical punched-out lesions.

Very rarely, osteosclerosis is described in association with untreated myeloma,<sup>3,73,167,252</sup> but usually other unusual features such as evidence of extramedullary hematopoiesis<sup>73</sup> and polyneuropathy<sup>3,167</sup> are present as well. Therefore, in some instances at least, the atypical bone changes may be due to some other disease, such as myelofibrosis,<sup>73</sup> rather than multiple myeloma.

A solitary plasma cell tumor of bone is found in perhaps 2 to 10% of the patients.<sup>170</sup> It appears most often as a cystic, soap-bubble-type lesion that is much larger and more irregular than the small, discrete lesions characteristic of "multiple" myeloma. At other times it has the appearance of a solitary, destructive lesion within the medullary portion of the bone.<sup>39</sup> Very rarely, new bone formation is seen. Although solitary lesions have in the past been regarded as comparatively benign, most patients have M-components in their serum, and, when followed for long periods of time, most develop diffuse

Fig 523 Lesions about the shoulder girdle in a patient with multiple myeloma (Courtesy of Dr David Bragg)

plasma cell myeloma,<sup>42</sup> even when the original lesion was radically excised or irradiated. Before a diagnosis of solitary plasmacytoma is made, areas of bone marrow at a distance from the single lesion should always be ex-

amined and careful, long-term clinical follow-up is essential.

"Rheumatoid" manifestations are sometimes observed.<sup>56</sup> These have been attributed to the deposition of amyloid in and about the joints. Occasionally, however, true rheumatoid arthritis and related joint diseases have preceded or have occurred simultaneously with multiple myeloma.<sup>86,256,264</sup> Their possible relationship to the development of multiple myeloma has been mentioned already (page 1600).

Involvement of the *nervous system* by multiple myeloma is largely a function of its proximity to skeletal structures. Thus root symptoms are common, and paraplegia due to compression of the spinal cord may occur. The latter is an extremely serious complication and usually requires immediate surgical decompression and local radiotherapy. Occasionally, cranial nerves may also become involved by tumor tissue. Root symptoms and peripheral neuropathies due to infiltration of these structures by amyloid have been described,<sup>249</sup> as have occasional instances of polyneuropathy and proximal myopathy in the absence of direct invasion of these structures by amyloid.<sup>41,170,230,249,254</sup> Such polyneuropathy appears to be similar to that seen in association with other neoplastic diseases. Multifocal leukoencephalopathy also has been reported.<sup>58</sup>

One of the most striking neurologic manifestations encountered in patients with multiple myeloma is *hypercalcemic encephalopathy*. This may present as confusion, delirium, or coma, usually following a period of weakness, lethargy, nausea, vomiting, and dehydration.<sup>69</sup> Such neuropsychiatric symptoms are more common in myeloma than in other diseases characterized by hypercalcemia, such as hyperparathyroidism.<sup>60,116</sup> About half of the patients with hypercalcemia develop EEG changes consisting predominantly of diffuse slowing and delta episodes, suggesting a disturbance of brain stem function.<sup>69</sup> While the relationship between hypercalcemia and central nervous system dysfunction is not a precise one<sup>68,100</sup> and some patients with high

Fig 52-4 Pelvic lesions in a patient with multiple myeloma

serum calcium have no obvious mental symptoms, whereas others with relatively lower calcium levels do, therapeutic measures designed to alleviate the hypercalcemia usually have a favorable effect on the neurologic manifestations. It is unclear to what extent other factors such as disturbed kidney function and acidosis contribute to the neuropsychiatric manifestations (see also Chapter 54).

*Extraosseous tissues* are frequently involved in multiple myeloma.<sup>39,179</sup> When both macroscopic deposits and microscopic infiltrates are included, extraosseous involvement may be seen in about two thirds of autopsied subjects.<sup>179</sup> Patients with the longest duration of illness tend to have the most widespread extramedullary disease. The commonest sites of involvement are the spleen,<sup>179,226</sup> liver,<sup>64,179,230</sup> lymph nodes,<sup>50,179,240</sup> and kidneys,<sup>179</sup> but infiltrates may also be encountered in most other tissues, such as thyroid and adrenal glands, ovary, testis, lung, pericardium, and intestinal tract.<sup>88,227</sup> Palpable hepatomegaly was reported in 40% of patients in

one series<sup>230</sup> and in 26% in another,<sup>2</sup> whereas hepatosplenomegaly<sup>230</sup> or splenomegaly<sup>2</sup> was seen only in about half that number. Discrete "solitary" plasma cell tumors may develop in soft tissues as well as in bone, most commonly in the respiratory tract or the oral cavity,<sup>179</sup> but they have also been described in the kidney, ovary, and intestine, or even the spleen.<sup>33</sup>

*Chronic renal failure* frequently becomes a prominent feature of the disease and is the end result of a number of interrelated factors.<sup>224</sup> Of prime importance is the filtration of large amounts of Bence Jones proteins by the glomeruli,<sup>39,47</sup> thereby presenting the proximal tubules with a massive reabsorptive load. In time, the tubules accumulate proteinaceous inclusion bodies, and cellular degeneration and impairment of tubular function soon follow.<sup>132,138</sup> The hyaline inclusion bodies within the epithelial cells have been shown to have the immunofluorescent staining properties of light chains.<sup>132</sup> In addition, large obstructing casts form along the entire length of the tubule, leading to disten-

sion and ultimate destruction of the whole nephron. These obstructing casts have been shown to contain albumin, fibrinogen, and  $\gamma$ ,  $\kappa$ , and  $\lambda$  chains, but no  $\beta_2$  globulin, IgM, or IgA.<sup>132</sup> Others have demonstrated the presence of amyloid-like fibrils within these casts and have suggested that they arise through a process of light chain degradation.<sup>83a</sup> The combination of hyaline or cancellated tubular casts usually surrounded by a syncytium of epithelial cells, accumulated hyaline droplets in epithelial cells, tubular atrophy, and, frequently, interstitial fibrosis and nephrocalcinosis constitutes the typical picture of 'myeloma kidney'.<sup>122a</sup>

Specific tubular reabsorption defects, including the adult Fanconi syndrome, have also been described as part of the nephrotoxic spectrum of Bence Jones proteins.<sup>57,67,94,110</sup> This suggests that some of these proteins have the capacity to interfere with specific tubular transport mechanisms. It is not known why some Bence Jones proteins are nephrotoxic while others are not.

In addition to Bence Jones proteins, several other factors are important in causing renal dysfunction.<sup>13 170 224</sup> Thus, *hypercalcemia* and *hypercalcaemia* due to bony destruction and immobilization may lead to all the manifestations of hypercalcemic nephropathy, while *hyperuricemia* (Chapter 54) due to increased cellular turnover, frequently aggravated by therapy, results in deposition of uric acid crystals in the distal tubules, collecting ducts, and ureters.

Sometimes acute renal failure occurs because of aggravation of chronic renal disease by dehydration or other insults. Thus intravenous pyelography is known to be associated with acute renal shutdown,<sup>129,170</sup> presumably because of the dehydration induced in preparation for this procedure. Of equal pathogenetic importance may be the capacity of some contrast media to induce Bence Jones protein precipitation in acid urine.<sup>129</sup>

Occasionally, *renal amyloidosis* complicates multiple myeloma. This will be discussed in a subsequent section (page 1636).

## Effects of Abnormal Proteins

While most of the clinical manifestations of multiple myeloma reflect the presence of malignant disease rather than the presence of abnormal proteins, some patients suffer from symptoms caused by the very large amounts of abnormal proteins, or proteins with unusual physicochemical properties.

*Undue sensitivity to cold* may be produced by myeloma proteins or protein complexes that undergo reversible precipitation at low temperatures. Such proteins are referred to as *cryoglobulins* (page 1640) and are most often associated with multiple myeloma and other plasma cell and lymphocyte dyscrasias. While patients with such proteins frequently are asymptomatic<sup>153</sup> they may have symptoms of cold urticaria, acrocyanosis, tingling, numbness, and a true Raynaud's phenomenon. Occasionally, trophic changes of the extremities, gangrene of digits, hemorrhagic manifestations, and thromboses of major blood vessels occur.<sup>170</sup>

The *hyperviscosity syndrome* (page 1625) is due to the presence of serum proteins with a high intrinsic viscosity. Most commonly this is seen in primary macroglobulinemia (Chapter 53), but occasionally it occurs in multiple myeloma with IgG or IgA proteins.<sup>21,119,139,196,234,239,259,262</sup> The high viscosity interferes with efficient circulation to the brain, eyes, kidneys, or digits. As a result, the fundi may show a very characteristic appearance with dilated venules and many hemorrhages; confusion and more severe central nervous system disturbances may develop quite suddenly. Signs of progressive peripheral vascular and cardiac insufficiency may also result from impaired circulation in the small capillaries. The diagnosis and treatment of this syndrome are discussed in Chapter 53.

*Hemorrhagic manifestations*, when not due to thrombocytopenia, are most commonly due to the ability of some M-components to interact with various proteins, including coagulation factors.<sup>44,127,159,163,180 239,251</sup> This type of complexing has been shown to in-

volve factors V, VII, and VIII, and prothrombin and fibrinogen. Abnormal fibrin aggregation and ultrastructure may be seen.<sup>44,127,194</sup> Increased factor VIII activity also has been reported.<sup>257</sup> In some patients, M-components may lead to abnormal platelet aggregation and function.<sup>44,159,181</sup> The nature of these defects is discussed in Chapter 35.

The immunochemistry and clinical manifestations of amyloidosis are discussed in Chapter 53 (page 1633). It is likely that amyloid associated with plasma cell dyscrasias is made up of fragments of light chains. Only about 10% of patients with multiple myeloma develop amyloidosis and the spectrum of disease ranges from cases with minimal, clinically insignificant deposits to those in which amyloidosis is the dominant feature. Amyloidosis appears to be particularly common in patients with IgD myeloma.<sup>72,80,103,266</sup>

### Associated Diseases

An unusually large number of patients with multiple myeloma appear to develop a second malignant disease, most commonly one involving the breast, biliary system, or bowel.<sup>170,244,258</sup> An apparently increased incidence of hematologic malignant conditions also has been reported, including acute myeloblastic, myelomonocytic or monocytic leukemia,<sup>125,172,193,222,248</sup> chronic myelocytic leukemia,<sup>204</sup> Kaposi's sarcoma,<sup>146</sup> and thymoma.<sup>133</sup>

### Laboratory Manifestations

#### Blood

Most patients with multiple myeloma eventually develop anemia that is usually of moderate severity, but may be severe; hemoglobin levels between 7 and 10 g/dl are most commonly found. The red cells in most of the patients are normochromic and normocytic and rouleaux formation may be prominent. The reticulocyte count is low. In most instances, defective red cell production can be demonstrated (Chapter 54). Occasionally, increased plasma volumes result in fictitiously

low hematocrits.<sup>120</sup>

While a normochromic, normocytic blood picture is the rule, exceptions have been noted. Thus the red cells are sometimes macrocytic and there may be megaloblastic changes in the bone marrow.<sup>32,105,128</sup> This may be due to folate deficiency,<sup>105</sup> or, occasionally, to true vitamin B<sub>12</sub> deficiency.<sup>32,128</sup> In other cases the macrocytosis has no discernible cause and such patients do not respond to specific vitamin therapy. Occasionally, when there is intestinal bleeding due to defective coagulation, amyloid infiltrates, vascular damage, or some other cause, iron deficiency anemia may develop. Polycythemia has also been reported in association with multiple myeloma,<sup>36,79,130,236</sup> but the exact relationship between these disease entities is unknown.

Enumeration of red cells may be difficult because of clumping and it may be impossible to make satisfactory blood smears because of rouleaux formation. This is usually due to the increased amount of globulin in the plasma and, in such an instance, dilution with normal saline or Gower's solution may provide a more satisfactory preparation. Because of clumping and rouleaux formation, blood grouping may be difficult. A rapid erythrocyte sedimentation rate is characteristically associated with red cell clumping and rouleaux formation, but, in the presence of cryoglobulins, the sedimentation rate may be zero.

The total leukocyte count usually is normal before the start of chemotherapy, but in some patients leukopenia may be present. Rarely the count is greatly increased.<sup>210</sup> The differential count may reveal no abnormality but in up to 50% of patients a mild neutropenia and a relative lymphocytosis are present and immature-appearing lymphocytes and plasma cells may be seen. The latter are common if a careful search of concentrated preparations is made.<sup>84</sup> In a few cases, numerous plasma cells have been observed, especially in the later stages of the disease. In one of our patients, 84% of the  $29.0 \times 10^9/l$  leukocytes were myeloma cells. The condition in such

a patient has been referred to as *plasma cell leukemia*.<sup>20,77s,114,168,197</sup> Its clinical course ranges from that of the terminal leukemic stage of otherwise classic multiple myeloma to an a priori fulminant course of acute leukemia,<sup>197</sup> characterized by hepatosplenomegaly, weakness, severe anemia, and bleeding manifestations. The protein abnormalities are similar to those of classic myeloma but the clinical course is generally acute or subacute and, except in rare cases,<sup>11</sup> no response to chemotherapy is observed.<sup>197</sup>

The platelet count usually is normal but sometimes is low. When a prolonged bleeding time is demonstrated in conjunction with moderate thrombocytopenia, it is more often due to a drug or M-component-induced functional platelet defect, or a vascular defect associated with cryoglobulins or the hyper-viscosity syndrome than to thrombocytopenia (Chapter 53)

### Bone Marrow

The characteristic findings are the "myeloma cells" (Plates VII, XXII, XXIII) which are present in virtually all patients with myeloma.<sup>14, 61, 170, 230, 232</sup> Occasionally a careful search is necessary to find these cells; this is probably attributable to the uneven way in which myeloma involves the marrow, especially in the early stages of the disease. Usually the marrow contains at least 5 to 10% myelomatous plasma cells, and when the number exceeds 15 or 20% the diagnosis is highly probable, especially if the cells occur in sheets similar to those characteristic of other types of tumor cells in the marrow. Nevertheless, the marrow picture must never be interpreted in the absence of other evidence of myeloma, since occasionally a similar picture may be seen in reactive plasmacytosis of various causes.

Typically the *myeloma cell* is moderately large (15 to 30  $\mu$ m), round, or ovoid, and contains a nucleus about 5 to 7  $\mu$ m in diameter. Occasionally myeloma cells are extraordinarily large and contain two or three nuclei. The nucleus is round, eccentrically placed,

and contains one or sometimes two nucleoli. The chromatin is not as fine as in the myeloblast nor as coarse as in the normal plasma cell, nor is the wheelspoke arrangement of the latter present. The cytoplasm may be basophilic and bright blue, or lighter in color.

There is, however, a great deal of variability from case to case (Plate XXII, E, F, G; Plate XXIII, F) as well as in the same case, and the cells may range from very anaplastic, immature forms to cells closely resembling normal plasma cells. At least part of the morphologic variability depends on the degree of functional differentiation of the cells. As the cells mature and develop the ability to synthesize gamma globulin, there is progressive accumulation of cytoplasmic RNA which is responsible for the characteristic basophilia and pyroninophilia of the cytoplasm. Such cells have a highly developed endoplasmic reticulum<sup>31,59</sup> and gamma globulins can be demonstrated within the endoplasmic cisternae.<sup>59,203</sup> Average molecular synthesis rates of 12,500 to 85,000 IgG molecules per minute per myeloma cell have been calculated.<sup>216</sup>

As in normal plasma cells, but particularly in those of inflammatory exudates, various types of inclusions may be seen in myeloma cells<sup>31,143</sup> (Plates VII, XXII). These include hyaline cytoplasmic spherules (*Russell bodies*), intranuclear inclusion bodies (similar hyaline spherules), and eosinophilic and PAS positive *granules*. All of these structures share a common electron density and osmophilic appearance when viewed under the electron microscope, and in most instances represent accumulations of gamma globulin. They are found in the nucleus, the Golgi apparatus, the intercisternal spaces, and inside the cisternae. Because of the light and electron microscopic identity of Russell (intracytoplasmic) and intranuclear inclusion bodies, it has been suggested that the latter are probably also of cytoplasmic origin.<sup>143</sup> "Mott cells," "grape cells," (Plate VII, H), and "morular cells" appear to be aggregations of Russell bodies. Some plasma cells also seem capable of phagocytosis.<sup>1</sup>

tempts have been made to correlate the hologic characteristics of myeloma cells the type of abnormal protein seen.<sup>61,142,178,233</sup> Such attempts are based on chemical differences between IgG and proteins and, particularly, on the higher hydrate content of the latter. In one of 72 patients with various plasma cell neoplasias, "flame cells" (Plate VII, J) and "giant cells" ("thesauocytes") (Plate VII, M) found only in those with IgA myeloma.<sup>178</sup> Others have partially confirmed findings.<sup>32,142,144</sup> The storage material consists of IgA globulin, possibly highly polymerized and therefore incapable of being degraded normally.<sup>245</sup> In addition to myeloma cells, histiocytes, monocytes, and lymphoid cells with plasmoid features have been described in the marrow of patients with multiple myeloma,<sup>141</sup> and occasionally this may make differentiation from some cases of lymphoma (see 51) difficult. Chromosome abnormalities<sup>113,34</sup> were discussed in Chapter 46.

### Immunologic Abnormalities

Typical M-components and/or Bence Jones proteins are demonstrable in virtually all patients with multiple myeloma. When they are not found, the adequacy of the study may be questioned.<sup>18,23,101,173,268</sup> Occasional myelomas without M-components have been reported from good laboratories<sup>48,60,111,173,205</sup> and the incidence appears to be less than 1%. Methods for the detection of M-components described earlier (page 1601). The cells are "non-secreting" have the same appearance as those of patients with other forms of myeloma, even as judged by electron microscopy. The question has been raised as to whether the non-secreting may be secreting protein not recognized by currently used methods.<sup>16</sup> The distribution of various immunoglobulin classes among myeloma proteins is usually proportional to the concentration of

their normal counterparts in the serum (Table 7-3). In most series,<sup>18,101,173,244</sup> the breakdown is approximately as follows: 50% IgG, 25% IgA; 25% have light chains only. IgD myelomas account for about 1% of all cases, and IgE<sup>77,114,168</sup> and IgM<sup>101</sup> myelomas are exceedingly rare. Thus only 75% of myeloma patients show prominent serum "spikes," light chains being much more difficult to demonstrate in the serum. The simultaneous presence of two M-components, most commonly IgG and IgA, has been documented in a small number of cases.<sup>17,52,209,211,221</sup>

Among IgG, IgA, and Bence Jones proteins,  $\kappa$  and  $\lambda$  chains are about equally distributed, but IgD myeloma is almost always associated with  $\lambda$  chains.<sup>72,76,102,103,193,266</sup>

Some interesting clinical correlations have been established for the various immunologic classes of myeloma.<sup>101</sup> Thus IgG myelomas appear to be associated with a greater reduction of normal immunoglobulins, more frequent infections, a higher serum level of M-protein, apparently slower tumor growth rates, and less hypercalcemia and amyloidosis than do other types. One of the outstanding features of IgA myeloma is hypercalcemia, and complicating infections are somewhat less frequent than in other varieties. Amyloidosis is not uncommon. IgD myelomas often occur in younger patients, Bence Jones proteinuria is usually marked, and hypercalcemia, amyloidosis, and renal failure are prominent features. Bence Jones myelomas are said to grow fastest of all and are associated with more osteolytic lesions, more hypercalcemia, and a higher incidence of renal failure and amyloidosis than either the IgG or IgA varieties. Survival of such patients is said to be relatively poor,<sup>37</sup> but this may simply reflect later detection of the disease. It has been suggested that myeloma without detectable M-components is even more poorly differentiated than Bence Jones myeloma and carries the worst prognosis of all.<sup>101</sup> Severe reduction of normal immunoglobulins is the rule.

Special protein properties such as cryoprecipitation, high intrinsic viscosities, and

amyloid deposition have been discussed elsewhere (page 1610).

### Other Laboratory Features

Many patients give evidence of renal failure with *azotemia*, high serum creatinine, and low creatinine clearance rates. The urine may contain, in addition to Bence Jones proteins, albumin, casts, and renal epithelial cells, but it is unusual to find red cells.<sup>141</sup> The concentrating functions of the kidney also may be impaired. In patients suffering from the Fanconi syndrome (page 1610), the urine may contain large amounts of amino acids, sugar, and phosphates. *Hyperuricemia* is a frequent complicating feature, as is *hypercalcemia*. The alkaline phosphatase is either normal or only slightly elevated.

### Diagnosis

The cytologic, clinical, and laboratory criteria for the diagnosis of multiple myeloma are listed in Table 52-1. In order to qualify for the diagnosis of multiple myeloma a patient must have one of the following combinations of criteria:<sup>51</sup>

1a and 1b

1a or 1b and either 2a, 2b, 2c or 2d.

Table 52-1 Criteria for the Diagnosis of Multiple Myeloma<sup>51</sup>

1	Cytologic criteria
a	Marrow morphology. Plasma cells and/or myeloma cells in excess of 10% when 1000 cells or more cells have been counted
b	Biopsy proven plasmacytoma either in bone or soft tissues
2	Clinical and laboratory criteria
a	Myeloma protein (M-component) demonstrable by electrophoresis of plasma
b	Myeloma protein (M-component) demonstrable by electrophoresis of urine
c	Roentgenologic evidence of osteolytic lesions. Generalized osteoporosis qualifies as a criterion if the marrow contains in excess of 30% plasma or myeloma cells
d	Myeloma cells in at least two peripheral blood smears

In addition, other diseases commonly giving rise to plasmacytosis ("collagen vascular" and immune complex diseases, cirrhosis, metastatic carcinoma, viral exanthems, should be excluded. Furthermore, if disease of bone is not evident, other features associated with myeloma, such as otherwise unexplained anemia, should be present. The presence of amyloid disease does not mitigate against the diagnosis of multiple myeloma.

### Treatment

#### General Measures

Patients with multiple myeloma need more support from their physicians than do most other cancer patients—severe pain is a common and almost continuous problem and there may be pathologic fractures; bacterial infections recur with distressing frequency and anemia, renal disease, and other manifestations may be troublesome; in addition, the disease is almost invariably fatal. In order to ease the patient's lot it is important to call attention to the improving prognosis with therapy, and it is necessary to alleviate exaggerated fears of pathologic fractures and to stress the dangers of immobilization with the consequent further skeletal demineralization and hypercalcemia. Above all, the physician must show a sincere and continuing interest in the patient and his inevitably recurring complaints and problems.

*Mobilization* is of prime importance, but is often made difficult by pain, fractures, and fear. The milder forms of pain frequently respond to salicylates and/or codeine, but sometimes more potent analgesics such as meperidine or opiates are necessary. However, salicylates must not be used when the platelet count is low or when platelet function is impaired. When pain is due to a readily identifiable bone lesion, *local* radiotherapy will almost always alleviate it (see below). *Orthopedic supports* for the spine, the rib cage, or the extremities often are helpful, but must be used for as short a time and as sparingly as possible, since they always lead to

some immobilization, disuse atrophy, and, eventually, habituation.

*Sodium fluoride* therapy has been used in the treatment of myeloma, since its chronic administration leads to positive calcium balance, increased mineralization of bone, and decreased pain in patients with various metabolic disorders of bone.<sup>30,199,202</sup> However, contrary to the initial reports,<sup>45,46</sup> double blind studies have demonstrated no beneficial effects of a subjective or objective nature.<sup>91</sup> Fluoride therapy undoubtedly leads to increased skeletal mineralization but this is due to the production of many layers of an inferior, fluffy bone that appears more sclerotic than normal,<sup>91</sup> but is, in fact, weaker.<sup>154</sup> Indeed, fluorosis may be detrimental to the clinical course of patients with multiple myeloma.<sup>91</sup> In addition, fluorides have toxic side effects which include nausea, diarrhea, gastrointestinal bleeding, skin rashes, and arthralgias. For all of these reasons the use of fluorides is not recommended.

### *Irradiation Therapy*

There is no evidence that radiotherapy influences the duration of survival but, as pointed out earlier, it remains the treatment of choice for individual painful bone lesions that do not respond to chemotherapy, for pathologic fractures, and for lesions that impair the function of vital structures. Relief of pain is prompt, pathologic fractures may heal, and impending compression of the spinal cord can be prevented.<sup>19,39,106</sup> Unfortunately, patients frequently return in a short time with trouble in another area and, while radiation may be given again, its use is ultimately limited by the development of bone marrow suppression, which also interferes with effective chemotherapy. Thus it is important to restrict the field of therapy and the total administered dose as much as possible, especially when the aim is relief of pain, rather than the treatment or prevention of a pathologic fracture. Total doses of less than 500 rads are frequently effective and seldom is it necessary to exceed 1500 rads.

### *Chemotherapy*

Since multiple myeloma is a generalized disease, systemic chemotherapy is the treatment of choice. Two alkylating agents, melphalan and cyclophosphamide, presently hold the greatest promise and are probably equal in their effectiveness.<sup>74,206</sup> The pharmacology and mode of action of these drugs are discussed in Chapter 55.

Most studies show that the proper use of these agents results in subjective and objective improvement in a majority of patients.<sup>51,74</sup> *Subjective changes* include significant pain relief, often within a few days of the start of therapy, and concomitant improvement in the patient's overall performance status as measured, for instance, on the Karnofsky scale.<sup>115</sup> *Objective changes* consist of (1) a significant decrease (>50%) in the concentration of M-components, including Bence Jones proteins<sup>51,74</sup>; (2) a decrease in the myeloma cell mass (see next paragraph);<sup>214</sup> which may be reflected in a lower percentage of marrow myeloma cells,<sup>51,74</sup> although the irregular distribution of the cells in the bone marrow sometimes makes interpretation of marrow data difficult; (3) reduction in the size of soft tissue masses<sup>148</sup>; and (4) repair of osteolytic lesions, x-ray-demonstrable recalcification of bone, or a general increase in bone density.<sup>7,71,108,208,252</sup> It must be stressed, however, that the radiographic appearance of bones may worsen initially and healing may not be evident for at least 6 to 12 months.<sup>74</sup> This initial radiographic deterioration must not be interpreted as lack of response to therapy, especially if other parameters indicate improvement. (5) Other objective parameters of improvement include a rise in hemoglobin levels or a decrease in transfusion requirements<sup>7,51,74</sup> and at least partial correction of hypercalcemia and uremia<sup>148</sup> as well as the normalization of immunoglobulin levels.<sup>3</sup> (6) Although groups of untreated patients have not been compared in a controlled study with patients receiving currently available forms of therapy, it does appear that the survival time of patients re-

sponding to melphalan or cyclophosphamide has been significantly lengthened.<sup>8,51,74,108,148</sup> The number of complete remissions unfortunately remains distressingly low; thus better modes of therapy will have to be developed.

There is a close relationship between the total tumor cell mass and the total body synthetic rate of M-components.<sup>242</sup> Changes in the latter can therefore be used to estimate the effectiveness of chemotherapy in slowing or arresting the rate of tumor growth. For practical purposes the measurement of changes in the concentration of serum M-components is a useful substitute<sup>74,105,118,242</sup> although such measurements frequently underestimate the changes in tumor size.<sup>242</sup> Since Bence Jones proteins have a much shorter half-life than do intact myeloma proteins (<1 day, versus 14 to 21 days for IgG, for example), a significant decrease in Bence Jones proteinemia and proteinuria is usually seen long before similar changes are evident in the concentration of intact myeloma proteins. A concomitant increase in the level of normal immunoglobulins is seen in only 20 to 30% of responding individuals,<sup>5</sup> and no increase occurs in patients refractory to therapy. It is of special interest that patients with a slow response, as measured by the drop in M-component concentration, seem to have a much better prognosis than those in whom a rapid drop in myeloma proteins is seen.<sup>100</sup> The latter group was found to fare little better than patients who did not respond at all.<sup>100</sup> With the exception of one report<sup>27</sup> there appears to be no consistent correlation between the L-chain type and response to therapy.<sup>8,171,206</sup>

*Melphalan* (L-phenylalanine mustard) has been used most extensively,<sup>7,26,38,51,62,74,108,109</sup> either alone or in combination with other agents, such as prednisone. Objective and subjective improvement is seen in about one third to two thirds of treated patients, depending in part on patient selection, the expertise of the physician, and, perhaps, on the mode of administration.<sup>8</sup>

Melphalan may be given either continuously or intermittently. Although the best

response rates reported for either method are similar,<sup>8,74,108,109,148</sup> comparative studies made within a single institution attest to the superiority of intermittent schedules, especially when melphalan has been combined with a second agent such as prednisone.<sup>8,82</sup>

When melphalan is used *intermittently*, a dose of 0.25 mg/kg/day is given for four days in conjunction with prednisone (2.0 mg/kg/day, also given for four days).<sup>8,82</sup> The treatment schedule is repeated every six weeks. The addition of procarbazine to this treatment program does not appear to increase the response rate significantly, or the duration of remission or survival.<sup>9</sup>

In *continuous regimens* the patient is generally started on 8 to 10 mg melphalan per day for seven to ten days.<sup>74</sup> The dose is then reduced to about 2 mg daily, but upward and downward adjustments in dose must be made, depending on the sensitivity of the normal marrow elements to the drug. A rest period of at least two weeks following the initial course of high-dose therapy has been recommended by some,<sup>108</sup> but others have warned of the danger of tumor and M-component rebound during this period.<sup>74</sup> Some clinics prefer to start with an initial dose as low as 4 mg daily and have reported results similar to those obtained with larger amounts of drug.<sup>148</sup>

The most important complication of melphalan therapy is bone marrow toxicity (Chapter 55). Other toxic effects are unusual, although anorexia, nausea, vomiting, and alopecia have been mentioned.<sup>206</sup>

*Cyclophosphamide*, another alkylating agent, is probably as effective as melphalan in the therapy of myeloma.<sup>11,38,121,122,151,206,220,228</sup> Dosage schedules vary considerably, ranging from 1.5 mg to 4.0 mg/kg/day. Intermittent cyclophosphamide therapy has been tried<sup>23,29</sup> and while it is clearly effective in the treatment of myeloma, the comparative value of continuous and intermittent therapy has not been tested. When used *intermittently*, 1 g/m<sup>2</sup> is given intravenously as a single "push" or 0.25 g/m<sup>2</sup>/day may be given by mouth on four consecutive

days. The treatment is repeated every three weeks. When giving cyclophosphamide in large doses, an adequate fluid intake (3 to 4 liters daily) must be ensured during therapy in order to decrease the risk of hemorrhagic cystitis and bladder fibrosis (Chapter 55).

At present it is impossible to decide whether melphalan or cyclophosphamide is the drug of choice in multiple myeloma. Bone marrow suppression appears to be approximately equal for both drugs, although the incidence of thrombocytopenia and bleeding may be slightly lower with cyclophosphamide.<sup>206</sup> Alopecia is probably more common with cyclophosphamide than with melphalan, as is hemorrhagic cystitis and eventual bladder fibrosis, but the latter complication can be prevented (see Chapter 55).

While both melphalan and cyclophosphamide are alkylating agents, their respective mechanisms of action probably differ to some degree, since patients resistant to one may still respond to the other.<sup>25,29,74</sup> Prolonged remissions have been obtained with the second agent after the patient had developed resistance to the first.<sup>74</sup>

### Other Agents

When used alone, the daily administration of prednisone is ineffective in the treatment of multiple myeloma.<sup>145</sup> *Intermittent high-dose prednisone therapy* may, however, be useful in patients who are poor treatment risks for alkylating agents because of severe bone marrow suppression or who are no longer responding to other agents.<sup>218</sup> The use of prednisone in conjunction with alkylating agents has already been mentioned.<sup>8,51,82</sup> Whenever possible, steroids should be used in large doses intermittently since continuous or even alternate-day regimens are associated with complications such as cushingoid changes, uncontrolled diabetes, recurrent infection, and gastrointestinal problems.<sup>8</sup> *Urethane* (ethyl carbamate) was used extensively prior to the introduction of alkylating agents and was reported to produce objective changes in 20% of treated pa-

tients.<sup>117,136,170,212</sup> One controlled trial failed to show any benefit,<sup>107</sup> but the results of this study have been criticized by some.<sup>74</sup> Use of the drug has generally been abandoned because of toxic and unpleasant side effects,<sup>170</sup> as well as the availability of better agents.

*Nitrosourea compounds* such as BCNU and CCNU are presently being tested in the treatment of myeloma.<sup>74</sup> *Purine and pyrimidine antagonists* as well as *folic acid antagonists* are ineffective.<sup>28</sup>

### Therapy of Complications

*Hypercalcemia* with its attendant dehydration and, frequently, renal failure requires prompt attention. Dehydration is due to many factors including the obligatory fluid loss of hypercalciuria, the tubular defect due to hypercalcemia, and the frequent nausea and vomiting that accompany this syndrome. The management of hypercalcemia must be prompt and vigorous. (1) The dehydration must be corrected immediately with sufficient parenteral fluids to assure a urine output of at least 2,000 ml/day. This in itself will increase calcium clearance by the kidneys. (2) Increased sodium clearance in man is accompanied by increased calcium clearance<sup>68</sup> and saline infusions may therefore be given, unless the patient is also suffering from congestive heart failure. Sometimes thiazides are used in conjunction with saline infusions. (3) Most myeloma patients with hypercalcemia promptly respond to prednisone in doses of 40 to 60 mg/m<sup>2</sup>/day.<sup>22,132,154,252</sup> If the patient is incapable of taking pills by mouth, equivalent doses of hydrocortisone may be given intravenously. A prompt drop in calcium levels is usually seen; patients suffering from hypercalcemic encephalopathy may show marked and rapid improvement. (4) When patients do not respond to other measures, the administration of inorganic phosphate salts has been recommended.<sup>87</sup> The hypocalcemic effect of phosphates is prompt, often occurring within hours of the intravenous administration of 1 liter of a 0.1 M solution of disodium phosphate and mono-

potassium phosphate. Daily oral therapy with 1 to 3 g of phosphate given as the disodium or dipotassium salt is also effective in maintaining normocalcemia. During phosphate therapy it is important to measure calcium levels frequently in order to prevent hypocalcemia. It may also be necessary to monitor the electrocardiogram for prolongation of the QT interval. The major disadvantages of phosphate therapy are metastatic calcifications,<sup>22a,235</sup> and diarrhea if the salts are taken by mouth. (5) Refractory patients may also be treated with large doses of furosemide intravenously,<sup>241</sup> careful attention being paid to the replacement of fluids and electrolytes. This form of therapy is probably safe and effective when used under close supervision in a hospital, but a good deal of clinical experience is needed.

*Hyperuricemia* and *hyperuricosuria* frequently contribute to renal failure and should be treated with adequate fluids and allopurinol, a xanthine oxidase inhibitor that reduces serum and urine uric acid levels regardless of the underlying cause<sup>178</sup> (Chapter 54). The usual dose is 300 to 600 mg daily. Since effective treatment of multiple myeloma will invariably exaggerate the problems of hyperuricemia, chemotherapy should be withheld until adequate renal function has been restored.

*Immunoglobulin therapy* has been advocated by some as prophylaxis against bacterial sepsis<sup>55</sup> but has been shown to be ineffective,<sup>217</sup> probably because of the increased fractional catabolic rate of normal immunoglobulins in patients with myeloma.

Symptoms due to the hyperviscosity syndrome (page 1625) respond well to plasmapheresis (Chapter 53).

*Spinal cord compression* is an extremely serious complication and requires *immediate* surgical decompression, followed by local radiotherapy in most instances.

## Prognosis

It has always been recognized that the course of multiple myeloma varies greatly.

Survival may be very short but sometimes it is very prolonged, spanning a decade or more with repeated exacerbations and remissions.<sup>38,74,141</sup> One remarkable patient has lived for more than 30 years following recognition of disease in the right ischium, continuing to do well despite other radiologically demonstrable lesions and an IgG M-protein.<sup>177</sup> Since the early 1960's, notable advances have been made in the treatment of multiple myeloma, both in terms of general management as well as through the introduction of effective therapeutic agents. These advances are reflected in the induction of at least partial remissions in as many as two thirds of all patients and perhaps by the prolongation of a comfortable and useful life. Thus, prior to the use of alkylating agents, the median survival time was 17 months from the onset of symptoms and only seven months from the onset of therapy<sup>160</sup>; in contrast, the median survival time is now between 24 and 50 months from the onset of therapy, representing a three- to seven-fold improvement.<sup>74</sup> However, it must be recognized in making this comparison that diagnosis now is made at an earlier stage of disease than it once was.

The blood urea concentration at the time of diagnosis is the single most important factor influencing prognosis.<sup>152</sup> The median survival time of patients with blood urea concentrations of 80 mg/dl or more is only two months, that of patients with concentrations of less than 40 mg/dl, 37 months.<sup>152</sup> Other indicators of a poor prognosis include proteinuria in excess of 40 mg/dl, a serum albumin concentration of less than 3 g/dl, and a hemoglobin of less than 7.5 g/dl. Bence Jones proteinuria correlates with azotemia but may not itself have adverse significance as regards prognosis.<sup>152</sup> As previously noted (page 1613), the type of M-protein may be of significance as regards survival; eg, in one study, death occurred within a year of diagnosis in 57% (8/14) of patients with IgA, in 38% (5/13) of patients with Bence Jones proteinuria but without a serum M-component, and in 21% (10/48) of those with IgG.<sup>89</sup>

# Macroglobulinemia, Heavy Chain Diseases, and Other Lymphocyte and Plasma Cell Dyscrasias

Macroglobulinemia  
Heavy Chain Diseases  
   $\gamma$ -Heavy Chain Disease  
   $\alpha$ -Heavy Chain Disease  
   $\mu$ -Heavy Chain Disease  
Amyloidosis  
"Benign" Monoclonal  
  Hypergammaglobulinemia  
Cryoglobulinemias

## Macroglobulinemia (Waldenström's Macroglobulinemia)

### Definition

The term "macroglobulinemia" includes a number of clinical conditions with a common serologic abnormality: the presence of a *monoclonal* macroglobulin which is produced by cell populations normally responsible for the synthesis of IgM globulin. Occasionally the term is used to describe a general increase in serum macroglobulins, i.e., a polyclonal elevation of serum IgM, but this practice leads to confusion and should be discouraged. Monoclonal macroglobulinemia is found under three circumstances: (1) as part of the plasma cell dyscrasia commonly identified as

*primary* or Waldenström's macroglobulinemia; (2) in association with certain malignant and progressive forms of lymphoma, nonreticular neoplasms, and, rarely, infections and inflammatory conditions (*secondary macroglobulinemia*); and (3) as a relatively stable serologic abnormality in the absence of any other identifiable disease (one form of "benign monoclonal gammopathy," page 1638).

### Etiology

A general discussion of possible etiologic factors in plasma cell dyscrasias is found in Chapters 46 and 52. A genetic predisposition has been suggested by family clusters of macroglobulinemia, as well as by the frequent occurrence of various immunoglobulin abnormalities and other immunologic abnormalities in the relatives of patients with macroglobulinemia.<sup>30,52</sup> The role of chronic inflammatory disease and nonreticular neoplasms<sup>29,41,56,62,68</sup> in the development of macroglobulinemia is the subject of much dispute.

### Clinical Features<sup>19,40 41,42,52,53,56,78</sup>

Macroglobulinemia is almost entirely a disease of the elderly, with a peak incidence

in the sixth and seventh decades. It occurs somewhat more commonly in males than in females. The disorder is frequently mild and is compatible with prolonged survival. Symptoms of vague ill health, weakness, and weight loss are common and may antedate the more serious manifestations by many years. As the disease progresses, *hepatomegaly*, *splenomegaly*, and *adenopathy* become prominent features and the clinical pattern becomes that of a lymphoma or of chronic lymphocytic leukemia. Eventually other tissues may become invaded by abnormal cells, including the lungs,<sup>58,75</sup> kidneys,<sup>52,59</sup> and central nervous system.<sup>52,54</sup>

Involvement of the *central nervous system* may be accompanied by high concentrations of macroglobulins within the cerebrospinal fluid.<sup>54</sup> Malabsorption due to the deposits of macroglobulins within the *intestinal wall* has also been reported.<sup>73</sup> In contrast to multiple myeloma, *bone pain* is not a prominent symptom and punched-out bone lesions are rarely seen.<sup>41,57,92</sup> Diffuse osteoporosis has been observed but may in many instances only reflect the patient's age.

*Renal disease* is much less common than in multiple myeloma,<sup>49,59,89,97</sup> even in the presence of Bence Jones proteinuria. The latter occurs in perhaps 10 to 30% of patients.<sup>52,59</sup> Occlusion of tubules by casts is extremely uncommon. The reason for this is unclear but may include the absence of contributing factors such as hypercalcemia and hypercalciuria. Renal amyloidosis is rare,<sup>31,59</sup> but uric acid nephropathy and interstitial infiltration with malignant cells do occur.<sup>59,97</sup> Occlusion of glomerular capillaries by subendothelial deposits of aggregated IgM proteins can be a striking finding.<sup>59</sup> Precipitation in these areas may be related to the euglobulin nature of macroglobulins, their high intrinsic viscosity, and the slow perfusion of capillaries. It is not known to what extent these deposits interfere with renal function.

*Amyloidosis* is rare and involves primarily the liver, spleen, and parenchymal organs.<sup>31,34,56,63</sup> This contrasts with multiple myeloma, in which amyloid deposits are

found primarily in the mesenchymal tissues such as muscles and the cardiovascular system (page 1634). Amyloid arthropathy has been described.<sup>34</sup>

Patients with Waldenström's macroglobulinemia frequently have decreased levels of *normal immunoglobulins* and suffer from defects in both primary and secondary antibody production.<sup>20,27,56,64,70</sup> Occasionally these defects may be severe.<sup>64</sup> The response of lymphocytes to PHA may be markedly impaired.<sup>79</sup>

### *Clinical Manifestations Caused by Abnormal Proteins*

Perhaps half the patients have clinical manifestations that are related to the specific physicochemical properties of the macroglobulins, including their high intrinsic viscosity, their ability to precipitate or gel on cooling, and their ability to participate in protein-protein interactions.

**THE HYPERVISCOSITY SYNDROME.** Viscosity is the property of fluid to resist flow. For protein solutions this resistance to flow is a function of the concentration and intrinsic viscosity of individual proteins in solution.<sup>9</sup> The intrinsic viscosity of a protein is in turn influenced by its molecular size and shape.<sup>9</sup> Since IgM molecules have a high molecular weight and an unusual shape—five projections extending outward from a central core (Chapter 7)—their intrinsic viscosity is great; macroglobulinemia, characterized by increased concentrations of such molecules, is therefore typically associated with increased serum viscosity. The serum viscosity may be further increased by the tendency of IgM molecules to aggregate,<sup>9</sup> while the viscosity of whole blood is influenced, in addition, by the tendency of protein-coated red cells to adhere to each other in rouleau formations.<sup>91</sup> These latter effects are enhanced by any decrease in velocity gradients and may account for the prominence of certain sites in the symptomatology of the hyperviscosity syndromes (see below).

While Waldenström's macroglobulinemia

is the most common cause of serum hyperviscosity, accounting for 85 to 90% of all cases,<sup>9</sup> the hyperviscosity syndrome is also noted in patients with myeloma (Chapter 52). Most frequently in myeloma the M-component is IgA, presumably because of the known tendency of IgA proteins to polymerize,<sup>9</sup> but occasionally IgG M-components lead to increased serum viscosity because of unusually high concentrations,<sup>11,52</sup> the presence of molecules with unusual (asymmetric) configurations,<sup>52</sup> or the presence of circulating aggregates of IgG M-components.<sup>6,9,13</sup> Rarely, serum hyperviscosity is noted in "connective tissue diseases" such as rheumatoid arthritis and in patients with cryoglobulins.<sup>9</sup>

The viscosity of serum is usually measured in a simple device, such as the *Ostwald viscosimeter*.<sup>28</sup> The time required for a constant volume of fluid to flow through a capillary tube is determined and is compared to the flow rate of water. The relative viscosity of normal serum (the flow time of serum divided by the flow time of water) ranges between 1.4 and 1.8.<sup>9,28</sup> It is important to make all measurements under identical conditions of pressure and temperature (usually at 37° C). A rapid screening test that uses a red cell pipette as the viscosimeter has been developed.<sup>93</sup> This test works equally well with plasma or serum and gives similar results at 37° C and at room temperature.<sup>93</sup>

The signs and symptoms of the hyperviscosity syndrome are related to the circulatory disturbances caused by the increased resistance of blood to flow. These disturbances are readily appreciated on examination of the fundi, where characteristic "link-sausage effects," consisting of alternating bulges and constrictions, are seen within the retinal veins.<sup>28,29,53</sup> Hemorrhage and exudates are also noted and visual impairment is not uncommon. Protean and everchanging neurologic manifestations, ranging from headaches, dizziness, and vertigo to somnolence, stupor, and coma, are the result of intracerebral vascular occlusions.<sup>9,28,80,94</sup> Patients may develop pareses of varying severity and Jacksonian or generalized seizures. Cere-

brovascular hemorrhage may occur secondarily. Profound, persistent deafness occurs, apparently due to thrombosis of the venous system of the inner ear.<sup>2</sup> Occlusive changes in small vessels elsewhere, due either to hyperviscosity or perhaps to cryoprecipitation, may lead to progressive peripheral neuropathies (Bing-Neel syndrome) and myelopathies.<sup>22,23,42,88</sup> Myopathies have also been described.<sup>69,87</sup> It has been suggested that elderly patients with polyneuropathies of unknown cause should always be suspected of having macroglobulinemia.<sup>89</sup>

Occasionally cardiac failure is precipitated in the elderly.<sup>9</sup> This appears to be related to hyperviscosity but may be aggravated by an increased plasma volume,<sup>53</sup> which develops in excess of that required to compensate for a decreased red cell mass<sup>53</sup> and bears a linear relationship to the relative serum viscosity.<sup>53</sup>

Hematologic complications of hyperviscosity include bleeding manifestations, which are aggravated by other effects of macroglobulins on the clotting system (see below). A relationship between erythrocyte life span and serum viscosity has been noted in some patients.<sup>18</sup>

Subjective symptoms include weakness, fatigue, and anorexia.

The threshold at which clinical symptoms occur, as well as the major target organ affected, differ from patient to patient.<sup>9</sup> However, patients with a relative serum viscosity of 2 to 4 are rarely symptomatic; many if not most patients with levels between 5 and 8 and nearly all with levels of 8 to 10 have symptoms. At relative viscosities of 10 or more all patients are symptomatic.<sup>9</sup>

The treatment of hyperviscosity syndromes will be discussed later (page 1629).

**CRYOGLOBULINS.** When a macroglobulin has the properties of a cryoglobulin (page 1640), the clinical manifestations are those of cold sensitivity, Raynaud's phenomenon, and peripheral vascular occlusion precipitated by cold. Monoclonal cold agglutinins are properly part of the macroglobulinemia spectrum but are discussed separately in Chapter 27. Occasionally, macroglobulins that are both

cryoglobulins and cold agglutinins are found.<sup>31,54</sup>

**PROTEIN-PROTEIN INTERACTIONS.** *Bleeding diathesis* results in the formation of complexes between macroglobulins and specific clotting factors such as factor VIII.<sup>16,60,61,68,69</sup> Reduced levels of factors II, V, VII, X, and XI have also been described.<sup>68</sup> Other factors contributing to the bleeding diathesis of macroglobulinemia include interference of macroglobulins with platelet function. This abnormality appears to be due to the coating of platelets by macroglobulins.<sup>45,65,69</sup> Abnormal platelet factor 3 activity has been noted.<sup>45</sup> The role of vascular damage due to increased serum viscosity, cryoprecipitation, and immune complex formation was mentioned previously.

All of these factors, in addition to thrombocytopenia (see below), result in a considerable amount of *bleeding*, particularly from the mucosae of the mouth, nose, and intestinal tract,<sup>55,61,69</sup> but bleeding from the skin may also occur. Purpura is often seen; it involves the legs predominantly. There may be prolonged bleeding at sites of minor injury. Sometimes hemorrhages involve vital areas such as the brain.

## Laboratory Findings

### The Blood

*Anemia*<sup>1,18,52</sup> is the most common presenting finding in patients with symptomatic macroglobulinemia and may become very severe. A combination of factors is responsible, including inadequate red cell production,<sup>18</sup> hemolysis,<sup>1,52</sup> and blood loss,<sup>18</sup> especially from the gastrointestinal tract. As mentioned previously, patients with an increased plasma volume due to hyperviscosity may have factitiously low hemoglobin levels.<sup>53</sup> The blood smear is usually normochromic normocytic, but rouleaux formation is often pronounced. Erythrophagocytosis has been described.<sup>44</sup>

*Leukocyte counts* are usually within the normal range, but, in some patients, neutro-

penia, as part of a general pancytopenia, has been observed. Terminally the peripheral blood may be flooded with malignant lymphoid cells that resemble those seen in the marrow (see below).

*Thrombocytopenia* is found in about half the patients suffering from a bleeding diathesis.<sup>68</sup>

*Hyperuricemia* may be present.

### Bone Marrow

It is not unusual for bone marrow punctures to result in a "dry tap." Usually this is due to the great cellularity of the marrow combined with the increased viscosity of the tissue fluid in which the cells are embedded.<sup>42</sup> *Lymphoid cells* more closely resembling lymphocytes than plasma or myeloma cells (Plate XXIII) are the predominant cell forms, but the picture is usually pleomorphic, with varying numbers of small lymphocytes showing little cytoplasm, naked nuclei, reticulum cells, and plasma cells. The last are usually too few to support a diagnosis of multiple myeloma. When the cytoplasm of lymphoid cells is sufficiently plentiful to be visible, it is often very basophilic. The periodic acid-Schiff (PAS) staining reaction frequently is positive, indicating the presence of abundant polysaccharide. The PAS staining material sometimes takes the form of globules ("grape cells"). The nucleus occasionally contains one or two nucleoli. In some cases eosinophilia has been reported, but a characteristic feature is the presence of large numbers of *basophils* and *tissue mast cells* interspersed among the other malignant cells.

### Protein Abnormalities

A markedly increased sedimentation rate and the rouleaux formation mentioned above may be the first clues to the presence of a protein abnormality. The diagnosis is confirmed by electrophoresis that reveals a *homogeneous spike* (M-component) with  $\beta$  to  $\gamma$  mobility, and by immunoelectrophoresis that establishes the IgM nature of the spike (Fig. 52-1,F). The macroglobulin contains ei-

ther  $\kappa$  or  $\lambda$  chains,  $\kappa$  chains being the more common.<sup>52</sup> Ultracentrifugation reveals a homogeneous IgM protein with a sedimentation coefficient of 19S and smaller amounts of more rapidly sedimenting components. IgM levels usually vary between 1.0 and 12 g/dl, and account for 20 to 70% of the total protein concentration.<sup>52</sup> The monoclonal IgM may be demonstrated in the cytoplasm of producing cells by immunofluorescence techniques, and is found on the surface of most proliferating lymphoid cells and on many circulating lymphocytes.<sup>72</sup>

*Urinary Bence Jones proteins* are found in up to a third of all patients and are identical to the light chains of the M-components.

The majority of macroglobulins are euglobulins and therefore give a positive reaction in the *Sia water test*,<sup>50,52,76,89</sup> especially when the protein is of  $\gamma$  mobility. In macroglobulinemic sera of  $\beta$  mobility the reaction to the *Sia water test* usually is negative.<sup>46,96</sup> Unfortunately, the test is not completely specific for macroglobulins, since certain IgG proteins also behave as euglobulins and will therefore give a positive reaction.

Some of the macroglobulins behave as *cryoglobulins* (page 1640) and yield either a whitish precipitate or a slightly turbid gel on cooling. A few have *cold agglutinin* activity (Chapter 27).

Some increase in relative serum viscosity is found in about two thirds of patients tested,<sup>52</sup> but only half of these will show clinical manifestations of the hyperviscosity syndrome (page 1626). Sometimes it is necessary to carry out viscosimetric determinations at various temperatures in order to show increased serum viscosity.<sup>87</sup>

Occasionally macroglobulins behave as *pyroglobulins* that precipitate on heating to 50 to 60° C but do not redissolve on cooling or further heating.<sup>63,66,85</sup> Most pyroglobulins are detected when serum is heated to 56° C in order to inactivate complement. Some macroglobulins have *anti-human IgG* activity.<sup>71</sup>

A significant number of sera from patients with Waldenström's macroglobulinemia con-

tain *low molecular weight (7S) IgM* (page 313) in addition to the typical 19S M-component.<sup>7,14,84</sup> and some produce  $\mu$  heavy chains, which apparently have lost the ability to combine with light chains.<sup>7</sup> In addition, Fab fragments, ie, fragments consisting of the amino-terminal end of the heavy chain plus its disulfide-linked light chain (Figs. 7-9 and 7-10) may sometimes be found in the urine.<sup>37</sup> A small number of macroglobulinemic patients with more than one M-component also have been described, including  $\gamma$  heavy chain fragments,<sup>43</sup> additional monoclonal IgM proteins,<sup>38,39</sup> and IgG and IgA M-components.<sup>39,57</sup>

### Differential Diagnosis

The diagnosis of macroglobulinemia is established on the basis of the characteristic serum protein abnormality and the typical changes in the blood and marrow. If there is no lymphadenopathy, hepatosplenomegaly, or obvious bone marrow abnormality, and if the concentration of the M-component does not increase over a period of years, the diagnosis of "*benign monoclonal gammopathy*" (page 1638) may be justified. Since macroglobulinemia frequently occurs in association with various malignant conditions<sup>42,52,62</sup> ("secondary macroglobulinemia"), a careful search for such conditions must always be carried out.

### Pathology<sup>24,51,52,56</sup>

Proliferation of abnormal lymphocytoid cells leads to enlargement of the spleen and lymph nodes and dense infiltrations in the periportal zones of the liver, in the kidneys, and throughout other viscera. In contrast to the findings in other lymphomas and leukemias, the lymph node architecture is largely preserved.<sup>44,56</sup> Infiltration of the small intestine and mesenteric lymph nodes is found to be associated with gastrointestinal manifestations such as diarrhea.<sup>12</sup> The central nervous system may also be infiltrated. The appearance of the lymphocytoid cells and the

Multiple myeloma and macroglobulinemia (Wright's stain,  $\times 1000$ ) A-F, Varieties of cells in the bone marrow of patients with multiple myeloma. F is from a patient with light chain myeloma. G and H are from the bone marrow of patients with Waldenström's macroglobulinemia. In G are shown a binucleated cell with nucleoli and shedding cytoplasm as well as abnormal lymphoid cells. In H, abnormal lymphoid plasma cells are seen, as well as a tissue mast cell.

bone marrow findings have been described previously (page 1627).

## Treatment

In the early stages, the disease may be stable or slowly progressive and no treatment is necessary. Later, anemia, bleeding manifestations, massive organomegaly, and symptoms related to hyperviscosity constitute the major indications for therapeutic intervention.

## Alkylating Agents

Alkylating agents are the drugs of choice in the treatment of Waldenström's macroglobulinemia. Chlorambucil,<sup>5,17,52,56</sup> melphalan,<sup>52</sup> and cyclophosphamide<sup>10,15,52</sup> have been used, and objective responses are seen in most treated patients. Such objective responses include reduction in the size of lymph nodes, liver, and spleen; decrease in M-component levels and reduction in serum viscosity to asymptomatic levels, as well as increased hemoglobin levels.

*Chlorambucil* has been used most frequently. Treatment is initiated with 6 to 8 mg daily; this dose is continued for two to four weeks. High-dose therapy (10 to 12 mg daily) carries the risk of marrow aplasia, which may be irreversible.<sup>52</sup> A maintenance dose of 2 to 6 mg daily is then instituted, and is continued indefinitely, since discontinuation leads to prompt relapse that may be difficult to control by reinstitution of drug therapy.<sup>56</sup> Some patients have been maintained on chlorambucil for many years, apparently in good remission. It is important to monitor marrow function by means of frequent blood counts during therapy in order to forestall unnecessary marrow toxicity.

*Cyclophosphamide* has been used in doses of 50 to 150 mg daily with equally good results.<sup>10,15,52</sup> High-dose intermittent regimens have not yet been evaluated in macroglobulinemia. Steroids are not generally

given, but have been used, especially in patients suffering from leukopenia and thrombocytopenia.<sup>73</sup>

## Plasmapheresis

All manifestations of the *hyperviscosity syndrome* respond to plasmapheresis.<sup>9,28,33,52,80,83</sup> The effectiveness of this procedure is due to two factors. Approximately 80% of all IgM is confined to the intravascular space<sup>28</sup> and the viscosity increment becomes progressively greater with each unit increase in IgM concentration.<sup>9,26</sup> Thus, at higher macroglobulin levels, relatively small reductions of serum macroglobulin concentrations (15 to 20%) may reduce the relative viscosity by 50 to 100%.<sup>9</sup> Often, however, it is necessary to remove at least half the plasma volume or more, in order to lower the serum viscosity significantly. As a guide to therapy, viscosity measurements should be made both before and after plasmapheresis. Once control of symptoms has been achieved, plasmapheresis must be repeated, since the effects of this procedure are temporary. Generally, 2 to 4 units of plasma have to be removed every week or two.<sup>9</sup> Temporary benefit has also been reported with the use of penicillamine or other chelating agents, presumably because these drugs can dissociate macroglobulin aggregates by reducing disulfide bonds.<sup>8,48</sup> Of greatest long-range promise is the use of alkylating agents (see above) and/or corticosteroids which, if effective, may lead to a prolonged reduction of serum viscosity to asymptomatic levels.

## Prognosis

Prognosis appears to be closely linked to response to therapy. In one study,<sup>52</sup> patients who responded to therapy had an average survival of four years from the time of diagnosis, whereas unresponsive patients lived only two years. Others have quoted overall average life expectancies of 38 to 40 months from the time of the first complaints.<sup>42</sup> Much

individual variation is seen, however, since the process is quite malignant in some and comparatively benign in others, with survivals of a decade or longer.<sup>19</sup>

## Heavy Chain Diseases

### Definition

Heavy chain diseases (HCD) are lymphocyte dyscrasias that are characterized by the malignant proliferation of immunoglobulin-producing cells and the concomitant synthesis of monoclonal proteins (M-components, page 1600), which have the immunochemical characteristics of incomplete heavy (H) chains. The abnormal cells are predominantly lymphocytes or plasma cells. The clinical manifestations of these diseases more closely resemble those of lymphomas than those of multiple myeloma. The first patient was described by Franklin in 1963<sup>117</sup> and since then an increasing number of cases have been reported.<sup>113</sup>

On the basis of structural differences within the heavy chain, five major immunoglobulin classes are recognized (heavy chain designations in brackets): IgG ( $\gamma$ ), IgA ( $\alpha$ ), IgM ( $\mu$ ), IgD ( $\delta$ ), and IgE ( $\epsilon$ ) (see Chapter 7 for details). So far only  $\gamma$ -,  $\alpha$ -, and  $\mu$ -heavy chain diseases have been reported;  $\delta$ - and  $\epsilon$ -heavy chain diseases have not yet been encountered. Since the clinical manifestations vary considerably, depending on the heavy chain class,  $\gamma$ -,  $\alpha$ -, and  $\mu$ -heavy chain diseases will be discussed separately.

### $\gamma$ -Heavy Chain Disease ( $\gamma$ -HCD)<sup>102,105,109,113,117,127,</sup>

145, 147, 148, 150, 152

### Clinical Features

During the 10 years following Franklin's initial description, approximately 30 cases of  $\gamma$ -HCD have come to light.<sup>113</sup> The disease has been reported in Caucasians, Negroes, and Orientals. There is a slight male-over-female preponderance. The age incidence has ranged between 18 and 76 years, but only four of 30 patients were under the age of 40.

The initial clinical manifestations may develop rapidly but more frequently are gradual in onset. *Lymphadenopathy*, *anemia*, and *fever* are the most common presenting features, but many patients also have *hepatosplenomegaly*. As the disease progresses, lymphadenopathy and hepatosplenomegaly become even more frequent and pronounced. Cervical, axillary, intrathoracic, and intra-abdominal nodes are most frequently involved,<sup>102</sup> but, occasionally, peripheral lymphadenopathy is absent.<sup>102</sup> *Palatal erythema and edema*, similar to those of infectious mononucleosis, are often seen and may give rise to respiratory difficulties. The palatal findings are probably due to involvement of the nodes of Waldeyer's ring. Recurrent bacterial *infections* are common and are the most frequent cause of death. *Bony lesions* similar to those of multiple myeloma appear to be rare, but have been reported.<sup>102,113</sup>

As in other plasma cell dyscrasias, a good number of patients with  $\gamma$ -HCD appear to have *associated diseases* with autoimmune features, such as lupus erythematosus, rheumatoid arthritis, Sjögren's syndrome, pulmonary fibrosis, myasthenia gravis, thyroiditis, and hemolytic anemia.<sup>113,123,138,150</sup> In addition, an antecedent history of chronic tuberculosis and cholecystitis has been reported.<sup>113</sup> In other patients, polyclonal hypergammaglobulinemia preceded the discovery of the M-component.<sup>109,117</sup> It is not known whether these conditions and HCD are etiologically related, but the possibility must be considered. Viral particles were seen in the tissues of one subject.<sup>117</sup>

### Laboratory Findings<sup>113</sup>

#### *The Blood*

Anemia is a universal finding. About two thirds of the patients have leukopenia that is usually due to granulocytopenia, and, in an equal number, atypical lymphocytes or plasma cells are seen in the blood smear. In patients with terminal illness the latter cells may occasionally be so frequent as to lead to the diagnosis of "plasma cell leukemia"

(Chapter 52). Eosinophilia was noted in two of the initial patients, but this finding has not been prominent in most reports.<sup>102</sup> About half the patients have thrombocytopenia. The ESR may be elevated. Hyperuricemia may be present.

### **Bone Marrow**

The bone marrow specimen is occasionally completely normal but usually shows an increase in plasma cells and/or lymphocytes and reticulum cells. Eosinophilia has been noted in combination with the other findings or, occasionally, as the sole abnormality. Biopsy or necropsy examination of lymph nodes and other involved organs has shown a similarly pleomorphic picture. An inaccurate pathologic diagnosis of Hodgkin's disease or a "granulomatous condition" is not uncommon in the early stages of the disease. Amyloid deposits have been discovered occasionally on postmortem examination.

### **Serology<sup>102,113</sup>**

The diagnosis of  $\gamma$ -HCD is generally based on the discovery in the serum and/or urine of an abnormal protein migrating in the  $\gamma$  to  $\beta$  region in conventional electrophoresis. On immunoelectrophoresis, these proteins are reactive with anti- $\gamma$  sera but not with antisera to Fab fragments (Chapter 7) or L (light) chains. In about half the patients the serum component is present in amounts greater than 2 g/dl; in the remainder the concentration is less. In most instances the spike is quite broad and heterogeneous and is accompanied by depressed normal gamma-globulin levels.<sup>102</sup> A poor antibody response to bacterial antigens and depressed cellular immunity have been found in a few patients.<sup>102</sup> A Bence Jones protein, macroglobulin, and H-chain fragment were discovered concomitantly in one patient.<sup>122</sup>

### **Protein Abnormalities**

Structural studies of the abnormal proteins have revealed sedimentation coefficients of 3.5 to 4.0S and molecular weights of 45,000 to 80,000. The proteins are unusually rich in carbohydrates. Most proteins belong to the  $\gamma_1$  subclass (see page 309 for a description of IgG subclasses), but the other three sub-

classes ( $\gamma_2$ ,  $\gamma_3$ ,  $\gamma_4$ ) have also been seen.<sup>102,113</sup> The abnormal proteins are H-chain fragments of several structural types<sup>113</sup> (Fig. 53-1). There may be (1) massive deletion of Fd variable and Fd constant regions, with resumption of normal synthesis at residue 216 (Glu)<sup>114,131</sup>; (2) deletion of the hinge region only (residues 216 to 232)<sup>111</sup>; (3) deletions of the Fd variable, Fd constant, and hinge regions, with resumption of synthesis at a point beyond the hinge region<sup>105,115</sup>; and, finally, (4) proteins that look like enzymatic degradation products derived from longer H chains, whose sequences most commonly start in the hinge region.<sup>130,144</sup> The mechanisms responsible for the structural deletions of  $\gamma$ -chain fragments are not known.

Sometimes the protein abnormalities are more complex; thus, the serum of one patient contained a monoclonal IgG $\lambda$  protein with deletions in both heavy and light chains (est. mol. wt. 110,000) and free  $\gamma$  chain fragments; deleted  $\lambda$  chains (est. mol. wt. 15,000) were found in the urine. The deletions in both heavy and light chains occurred in their respective variable regions and appeared to be comparable.<sup>119</sup>

### **Treatment**

Treatment is often unsatisfactory. Local radiation to spleen and lymph nodes appears to be rapidly effective in reducing the size of the involved organs,<sup>102,117,127,136</sup> but usually the effect is transient. Prolonged beneficial effects are occasionally observed.<sup>136</sup> Alkylating agents have not been beneficial in doses and treatment schedules used to date,<sup>102,113</sup> except for transient responses in occasional patients.<sup>109,127</sup> A good response to prednisolone alone<sup>145</sup> and to vinblastine<sup>108</sup> has been observed in single patients. Combination drug therapy (nitrogen mustard, vincristine, prednisone, and procarbazine) appears to be promising.<sup>106</sup>

### **Prognosis**

Thus far, prognosis has been unfavorable, many patients having died within a matter of months from infections or other effects of the malignant condition, but some have survived for five years and more.<sup>113,149</sup>

Fig. 53-1 Schematic representation of some deletion patterns currently recognized in  $\gamma$ -heavy chain disease. Fragments (below) are compared to normal  $\gamma_1$  heavy chain (above). Variable region (V), heavily shaded; hinge region, lightly shaded. Numbers refer to amino acid residues. CH 1, 2, 3 = constant regions. See Chapter 7 and Figure 7-9 for details of immunoglobulin structure. Deletions of heavy chain fragments indicated in light lines. See text for details of fragment structure. (Adapted from Frangione and Franklin<sup>114</sup>)

### $\alpha$ -Heavy Chain Disease ( $\alpha$ -HCD)<sup>113,133,139,141</sup>

#### Clinical Features

$\alpha$ -HCD was first described by Seligmann in 1968<sup>140</sup> and seems to be the most common form of HCD.<sup>133,141</sup> In contrast to  $\gamma$ -HCD,  $\alpha$ -HCD has a predilection for younger age groups, including children. The areas of involvement correspond to the main sites of secretory IgA production, particularly the gut, or occasionally, the respiratory tract.<sup>113,133,141</sup> Infiltration of the lamina propria of the intestine and of abdominal lymph nodes with plasma cells, lymphocytes, and reticulum cells is a characteristic feature of the disease and gives rise to severe malabsorption, diarrhea, and hypocalcemia. In most cases the infiltrate is confined to the lamina propria of the small intestine, but occasionally involvement of the rectum or stomach and spread to the bone marrow and even to the postnasal space are seen.<sup>133</sup>

$\alpha$ -HCD is most commonly associated with a condition previously identified as "Mediterranean lymphoma" because the first described

patients were non-Ashkenazi Jews or Israeli Arabs.<sup>134,139,140</sup> The disease does not appear to be restricted to these population groups, however.<sup>126,128</sup>

Whether  $\alpha$ -HCD is malignant from the beginning or starts as a benign hyperplastic process, perhaps in response to a high degree of intestinal infection,<sup>133</sup> is unknown. Some patients eventually develop reticulum cell sarcoma.<sup>133</sup>  $\alpha$ -HCD must be differentiated from nodular intestinal lymphomas (Chapter 51).

#### Laboratory Features

Since  $\alpha$ -HCD does not usually involve the marrow, changes in the blood are invariably due to other complications, such as malabsorption or bleeding. The serum alkaline phosphatase (intestinal isoenzyme) may be elevated.<sup>133</sup> A defect in systemic immunity has been demonstrated in two patients,<sup>133</sup> but local intestinal immunity has not been studied.

On electrophoresis  $\alpha$ -heavy chains usually

migrate in a broad peak with  $\beta$  to  $\alpha_2$  mobility. This is due to their tendency to polymerize, which may also explain the relatively low excretion of  $\alpha$ -chains in the urine, in comparison to  $\gamma$ -chains.  $\alpha$ -Chains may also be recovered from jejunal juice,<sup>126</sup> and this is sometimes the preferred method of diagnosis. On immunoelectrophoresis the protein reacts with anti- $\alpha$  sera but not with anti-light chain sera. Unfortunately many intact IgA myeloma proteins also do not react with antisera to light chains<sup>113</sup> and this, in addition to the low concentration of  $\alpha$ -chains in the urine, frequently makes diagnosis difficult. Only the  $\alpha_1$  subclass (Chapter 7) has been identified so far, even though most normal secretory IgA is of the subclass  $\alpha_2$ .<sup>133</sup>

A small bowel biopsy specimen will show the characteristic cellular infiltrates described above. The liver, spleen, and peripheral lymph nodes usually are not involved.

### Treatment

Therapy is usually unsatisfactory, but good responses leading to prolonged remissions have been reported with radiotherapy and prednisone,<sup>126</sup> as well as with cyclophosphamide.<sup>153</sup> Complete remissions of the disease after treatment with antibiotics alone have also been recorded.<sup>133,135</sup>

### $\mu$ -Heavy Chain Disease ( $\mu$ -HCD)<sup>101,107,112,113,124</sup>

#### Clinical Features

This is the rarest of the heavy chain diseases and only a few patients have been described.<sup>101,103,112,120,124</sup> Most but not all<sup>101a,102a</sup> have had long-standing chronic lymphocytic leukemia (CLL)<sup>107,113</sup> or non-Hodgkin's lymphoma.<sup>118,120</sup> The disease is manifested primarily by visceral organ involvement including hepatomegaly, splenomegaly, and enlarged abdominal nodes with little, if any, peripheral lymphadenopathy. One patient had amyloidosis and two had suffered pathologic fractures. Another patient developed a  $\mu$ -chain fragment in association with an ill-defined lymphoma-like disorder characterized by an indurated ulcerating lesion over the left pa-

rotid gland and massive splenomegaly.<sup>120</sup> In most instances, the protein was discovered in the later stages of the disease process and it is not known whether it was present from the beginning or whether its discovery is a bad prognostic sign. Prolonged survival has been observed after the diagnosis of  $\mu$ -chain disease was made.<sup>118,124</sup>

### Laboratory Features

In patients with CLL the main hematologic findings are those of the underlying disease (Chapter 49), except that strikingly vacuolated plasma cells are found in the marrow.<sup>113</sup>

The routine electrophoretic pattern does not reveal  $\mu$ -chain protein, but marked hypogammaglobulinemia usually is seen. Immunoelectrophoresis reveals a rapidly migrating protein reactive with anti- $\mu$  sera but not with antisera to light chains. The protein is not found in the urine, perhaps because of polymerization of the fragments,<sup>116</sup> but the serum protein appears to exist predominantly in the monomeric form.<sup>120</sup> Some patients had heavy Bence Jones proteinuria in addition to the heavy chain fragment,<sup>113,118</sup> and it has been suggested that an abnormality in H-chain synthesis, perhaps a deletion, may preclude normal H- and L-chain association in these instances.<sup>103,154</sup> Another patient produced, in addition, a monoclonal IgA protein.<sup>120</sup>

Therapy is directed at the underlying disease (Chapter 55).

## Amyloidosis

### Definition

Amyloidosis is a disease characterized by the presence of a homogeneous, eosinophilic material in various tissues throughout the body. The hallmark of these deposits is the amyloid fibril, which is readily identified by its green polarization birefringence following staining with Congo red, as well as by a unique x-ray diffraction pattern. The deposition of amyloid proteins in vital structures

is responsible for the replacement and destruction of the latter and, often, the eventual death of the patient. The term "amyloid" was introduced by Virchow because of the apparent affinity of the material for iodine, which suggested a resemblance to starch. Carbohydrates are now known to be a minor and relatively unimportant component of amyloid.<sup>200</sup>

### Classification (Table 53-1)

Amyloidosis was first described in association with chronic sepsis such as tuberculosis, and this form is now identified as "secondary amyloidosis." It soon became evident that material indistinguishable from this type of amyloid could also be identified in the myocardium and other tissues of certain individuals in the absence of chronic infection. Such patients are said to suffer from *primary amyloidosis*. Severe forms of this condition are

much less common than cases of secondary amyloidosis, but clinically undetectable deposits of amyloid are quite often seen in the elderly (*senile amyloidosis*).<sup>172,177,207,214,252,255</sup>

Amyloidosis is also found in association with various plasma cell dyscrasias, especially multiple myeloma, and this form of the disease most closely resembles primary amyloidosis. Familial forms of amyloidosis also have been described and often affect specific organ systems, resulting in polyneuropathy, nephropathy, or cardiopathy.

In the past much has been made of the differential organ involvement in primary and secondary amyloidosis. Thus, it was stressed that primary amyloidosis and amyloidosis occurring with multiple myeloma typically involved mesodermal tissues such as smooth and skeletal muscle and the cardiovascular system, whereas secondary amyloidosis involved primarily the liver, spleen, and kidneys. A great deal of overlap is seen, however.<sup>171,177,217</sup> and while clinical differences between primary and secondary amyloidosis are demonstrable in large series, they probably are no greater than the differences between individual cases within either category.<sup>217</sup> Existing differences in the deposition of amyloid may be related to differences in the precursor protein, and in its rate of synthesis or catabolism, or in the anatomic relationship between the cell producing the precursor protein and the cell producing the fibril from the precursor (see below).<sup>200</sup>

### The Nature of Amyloid<sup>191,199,209</sup>

The first chemical analysis of amyloid was made in 1859 and suggested that the material was a protein.<sup>189</sup> Since then there has been much controversy about the origin and chemical composition of amyloid.<sup>213</sup> A link between amyloidosis and the immune system had been suspected for many years because of the frequent association of amyloidosis with plasma cell dyscrasias,<sup>220,227,229</sup> the demonstration of an increased number of plasma cells in the marrow of some patients with primary amyloidosis,<sup>162</sup> and the association between chronic antigenic stimulation

**Table 53-1. Amyloidosis—Classification**

I	Primary amyloidosis

B	Familial amyloid cardiopathy
C	Amyloid nephropathy of familial Mediterranean fever
D	Familial amyloid nephropathy
E	Familial cutaneous amyloid
F	Familial medullary thyroid carcinoma producing amyloid

and so-called "secondary" amyloidosis.<sup>206,239,256</sup> In addition, immunofluorescence and other immunochemical studies occasionally revealed immunoglobulins or their component parts in amyloid.<sup>243</sup> However, it remained for electron microscopic investigations to reveal a fibrillar component of distinctive appearance<sup>178,179,236,245,246</sup> which was shown to be the structure responsible for the Congo red staining of amyloid and its birefringence under polarized light. X-ray crystallographic analysis subsequently demonstrated that these fibrils are composed of polypeptide chains arranged in an antiparallel conformation and a  $\beta$ -pleated sheet structure.<sup>182</sup> Eventually, ways were found to solubilize and purify these proteins<sup>193,195</sup> and this resulted in their physical, chemical, and immunochemical characterization.<sup>195,205</sup>

The major protein components of amyloid fibrils may be of immunoglobulin or non-immunoglobulin origin.

**AMYLOID OF IMMUNOGLOBULIN ORIGIN.** *Amyloid fibrils of immunoglobulin origin* are most frequently associated with plasma cell dyscrasias or with primary amyloidosis, but have also been found in patients with secondary amyloidosis.<sup>199,200,222</sup> The immunoglobulin nature of these fibrils has been proved conclusively by amino acid sequence analysis,<sup>197,249</sup> which revealed structures similar to those of Bence Jones proteins.<sup>200,249</sup> In addition, the sequence of amyloid fibrils derived from a given individual was found to be homogeneous, thereby indicating the probable origin of these fibrils from a single clone of immunoglobulin synthesizing cells. The molecular weights of fibril proteins range from 5,000 to 18,000,<sup>195,200,205</sup> whereas those of intact light chains are 22,500. Thus, in most patients with amyloidosis only fragments of light chains are contained in amyloid deposits and most of these appear to be derived from the amino terminal or variable portion (page 308) of the light chain, i.e., the portion involved in antigen binding. Since most antisera against light chains react with antigens in the constant (partially missing) region (page 308) of the molecule or with idiotypic determinants of the variable region, it is not

surprising that many workers were unable to confirm the immunoglobulin nature of amyloid by immunofluorescence and other techniques.<sup>200</sup> Occasionally, fibrils may contain either an intact light chain or a combination of intact light chains and light chain fragments.<sup>200</sup>

The source of amyloid fibrils is not always clear.<sup>199</sup> (1) They may be derived from circulating M-components such as Bence Jones proteins or from whole immunoglobulin molecules. This is almost certainly the case in amyloidosis associated with plasma cell dyscrasias. In this connection it is of interest that amyloid fibrils may be produced by proteolytic digestion of monoclonal light chains,<sup>196,218</sup> while in other situations Bence Jones proteins can be converted directly to amyloid fibrils by thermal treatment.<sup>199</sup> (2) Antigen-antibody complexes may be catabolized by macrophages and fibrils may be deposited in macrophage-rich organs, such as the liver and spleen, producing a distribution most commonly associated with secondary amyloidosis.<sup>199</sup> (3) Deletions in the light chain gene might result in fragments analogous to those seen in heavy chain disease (page 1631); or (4) there may be separate and disproportionate synthesis of variable and constant regions of light chains<sup>196,242</sup> leading to fibril formation.

**AMYLOID OF NON-IMMUNOGLOBULIN ORIGIN.** In some patients the amyloid deposits are derived from proteins that have no resemblance to immunoglobulins.<sup>165,183,196,199,215</sup>

This material has been referred to as A-component, nonimmunoglobulin acid-soluble fraction (ASF) or "amyloid of unknown origin" (AUO),<sup>200,214</sup> since the responsible protein has not yet been identified. These amyloid fibrils may be derived from proteins associated with immunoglobulins such as the J-piece, the secretory piece, or complement components (Chapter 7).<sup>200</sup> AUO is usually found in patients suffering from the secondary form of amyloidosis and may originate from a larger protein by proteolytic digestion.<sup>200</sup> While the structure of immunoglobulin-derived amyloid fibrils tends to vary from patient to patient, all

amyloid fibrils of unknown origin appear to have an almost identical N-terminal sequence.<sup>200,214,215</sup> A component which cross reacts with ASF has also been found in the sera of a small number (7%) of normal individuals and in the sera of a larger number (50 to 80%) of patients who suffer from conditions known to be associated with amyloidosis.<sup>215</sup> Sometimes smaller quantities of immunoglobulin proteins have been found in addition to the AUO.<sup>168,200</sup>

**OTHER FORMS OF AMYLOID.** Possibly a third form of amyloid has been identified in association with various endocrine tumors such as medullary carcinoma of the thyroid gland and insulinomas.<sup>221,232</sup>

**OTHER COMPONENTS OF AMYLOID.** Other components identified within amyloid deposits include fibrinogen, lipids, lipoprotein, complement components (especially in the secondary form), and polysaccharides.<sup>200</sup> Of special interest is the presence of small (8-nm) doughnut-like, pentagonal structures composed of five globular subunits surrounding a central cavity.<sup>167,192</sup> This morphologically distinct unit has also been shown to aggregate into rods with a 4-nm periodicity<sup>192</sup> and appears to consist of glycoproteins that are unrelated to the protein component of fibrils.<sup>191</sup> Antibodies against the pentagonal component cross-react with normal serum components migrating in the  $\alpha_1$  region.<sup>200</sup> By immunofluorescence techniques the material has been identified in all amyloid deposits studied so far.<sup>176</sup>

### Incidence

The prevalence of amyloidosis in the population at large is not known. Routine autopsy data from general hospitals show an incidence of about 0.5%,<sup>177</sup> but these data are probably falsely low because special stains are not routinely employed. In leprosy, chronic tuberculosis, and similar conditions, the incidence may be as high as 50%, and similarly high figures have been quoted for hereditary forms of amyloidosis associated with familial Mediterranean fever.<sup>177</sup> In selected populations of old people, such as those

suffering from senile dementia, the incidence may approximate 90%.<sup>244</sup>

### Clinical Features

The clinical manifestations of amyloidosis are determined by the distribution of tissue infiltrates. *Renal involvement* is the most common and potentially the most serious manifestation of amyloidosis and is the major cause of death in most series.<sup>169,171,181,217,230</sup> It is equally frequent in primary and secondary amyloidosis<sup>171,217</sup> and occurs as the major manifestation of the amyloid associated with familial Mediterranean fever.<sup>171</sup> The lower urinary tract and other urogenital organs also may be involved. Occasionally renal amyloidosis may be completely asymptomatic, but most patients exhibit proteinuria, which may be massive, and perhaps 60% of all patients eventually become nephrotic.<sup>177</sup> In addition to proteinuria, hyposthenuria and persistent hematuria may be found. Azotemia is a late manifestation of renal amyloidosis.

*Cardiac involvement* occurs in most patients (80 to 90%) with primary amyloidosis and in more than half of those with secondary amyloidosis.<sup>177</sup> It may also occur as a familial condition.<sup>187</sup> Amyloid infiltration of the heart typically results in enlargement without changes in the intracardiac volume, as occurs in heart failure from other causes. The stiff, thickened myocardium may yield cardiac catheterization data which are erroneously attributed to constrictive pericarditis. In addition to cardiac failure, manifestations of amyloid heart disease include conduction disturbances, arrhythmias, and symptoms of coronary artery insufficiency. The electrocardiogram often shows low voltage in the QRS complex. Heart failure due to amyloidosis may be quite intractable; in addition, some patients are quite sensitive to digitalis and may develop serious as well as lethal arrhythmias.<sup>175,233</sup>

*Gastrointestinal involvement* is common in all forms of amyloidosis. It occurs at all levels of the gastrointestinal tract and may lead to obstruction, diarrhea,<sup>188</sup> hemorrhage,<sup>169,209</sup> and secondary manifestations such as vitamin

$B_{12}$  deficiency,<sup>169,170</sup> malabsorption,<sup>169,188</sup> and protein-losing enteropathy.<sup>209,237</sup> Liver involvement occurs in virtually all patients with secondary amyloidosis and in most patients with primary amyloidosis.<sup>171,216</sup> Livers weighing 4 to 9 kg have been reported, but there is often little impairment of hepatic function and laboratory studies may reveal little or no abnormality.<sup>177</sup> The BSP test and serum alkaline phosphatase levels are the most useful laboratory procedures for assessing the function of amyloid livers.

The respiratory tract may be involved in about 20% of secondary amyloidosis patients and in the majority of patients with primary amyloidosis. Amyloid may involve the oral mucosa, tongue, gingiva, sinuses, and the area around the larynx, as well as the trachea, bronchi, and lungs.<sup>168,177,235</sup> The symptoms depend on the anatomic location of the amyloid.

Amyloidosis of the nervous system may result in peripheral neuropathy with sensory disturbances, painless ulcers, and weakness of the legs. The autonomic nervous system may also be affected, with sphincter disturbances, impotence, dyshidrosis, or orthostatic hypotension.<sup>177,226</sup>

The "carpal tunnel syndrome" with medial nerve compression and arterial insufficiency of the hands may result from infiltration of the carpal ligaments. Amyloid deposits may also involve joints in which they frequently produce symptoms that mimic those of rheumatoid arthritis.<sup>202,234</sup> Amyloidosis of various endocrine organs occurs occasionally. Virtually all other sites of the body may be involved with amyloid, in the form of either small infiltrates or large tumors.

Amyloidosis of the skin<sup>177,221</sup> is characterized by hyaline plaques which occur most commonly in skin folds such as the inguinal area. When the small vessels of the skin and mucous membranes are involved as well, diffuse purpura may be seen. Often profuse bleeding occurs after minor surgical procedures such as those performed for securing gingival or skin biopsy specimens. When amyloidosis occurs in association with plasma cell dyscrasias, defects in hemostasis due to

the latter (page 1610) may further aggravate the bleeding tendency. A few cases of amyloidosis with an acquired factor X deficiency have been described.<sup>166,253</sup>

Some patients with an underlying plasma cell dyscrasia suffer from a particularly severe form of dermal amyloidosis referred to as lichen myxedematosus or papular mucinosis.<sup>223,228,241</sup> In some cases a uniquely basic cationic M-component of the IgG class has been identified<sup>208</sup>; this has a strong affinity for constituents of normal skin.<sup>223,228</sup> It is not known whether these M-components have autoantibody activity towards normal skin or whether the interaction is a nonspecific one. In most patients with lichen myxedematosus, the skin disease becomes progressively worse and may on occasion appear as a prelude to multiple myeloma.<sup>233</sup> Resolution of skin lesions has been observed following successful therapy of the associated plasma cell dyscrasia with melphalan.<sup>185</sup>

### Laboratory Features

Because amyloid infiltrates may involve many organ systems a great variety of hematologic and biochemical abnormalities may be produced. Some of these are the result of underlying diseases such as chronic sepsis or a plasma cell dyscrasia. A diligent search must be made for the latter in all patients. Such studies must include electrophoretic examination of a concentrated urine specimen, since the presence of light chains in the urine is often the only demonstrable protein abnormality. An associated factor X deficiency should be looked for in patients with hemorrhagic tendencies.<sup>166,253</sup> Diagnostic features of plasma cell dyscrasias have been discussed previously (page 1614).

### Diagnosis

The diagnosis of amyloidosis is best confirmed by biopsy. Gingival biopsy is useful in more than half of all the patients, but rectal biopsy may be even more rewarding. Skin biopsies may provide positive evidence of the disease even in the absence of visible lesions.

Renal and hepatic biopsies carry a greater risk of serious hemorrhage, and rupture of the liver has been reported. Tissue sections should be stained with Congo red and examined under regular and polarized light. The appearance of areas exhibiting a characteristic green color together with dichroism constitutes almost specific histologic evidence for the presence of amyloid. Definitive confirmation requires electron microscopy.

The Congo red test, which was based on the increased rate of disappearance of this dye from the circulation of patients suffering from amyloidosis,<sup>177</sup> has been abandoned because of the occasional occurrence of severe toxic reactions and the greater specificity of histologic methods.

### Prognosis and Therapy

Because such a variety of clinical presentations are seen in amyloidosis, it is impossible to quote accurate figures regarding prognosis. In many series the prognosis is weighted because the disease was diagnosed late or at postmortem examination. In other series the underlying disease is the immediate cause of death. Nevertheless, one- to four-year survivals after diagnosis have been quoted in most larger series.<sup>177</sup> In rare instances of "secondary amyloidosis," regression of amyloid deposits has been noted after successful therapy of the underlying disease. Such patients have included occasional ones with chronic infections such as tuberculosis or osteomyelitis,<sup>212,250,251</sup> and occasionally those with tumors such as renal carcinoma.<sup>231</sup>

With the exception of the favorable effects of therapy in these few patients, no specific and efficacious form of treatment is currently available. In some patients with amyloidosis associated with plasma cell dyscrasias, attempts have been made to treat both conditions with cyclophosphamide or melphalan, but while it has been possible to lower the concentration of M-components in some patients, the clinical results have been disappointing.<sup>229,234</sup> Rare exceptions have been noted.<sup>210</sup> Attempts have also been made to treat primary amyloidosis patients with cyto-

toxic drugs, but with equally unsatisfactory results.<sup>164</sup> Steroids are of no use in treating patients with any form of amyloidosis, including amyloid nephrosis.<sup>177</sup>

## "Benign" Monoclonal Hypergammaglobulinemia

### Definition

When electrophoretically homogeneous immunoglobulins appear in the *absence* of malignant plasma cell dyscrasias or infection, the condition is referred to as "benign monoclonal hypergammaglobulinemia" (BMH) or "benign monoclonal gammopathy," a term initially proposed by Waldenström.<sup>292</sup> M-Components occurring in association with lymphoreticular malignant disorders such as lymphomas and leukemias are excluded from this definition, but those found in association with other forms of malignant conditions are not. In these cases the term "benign" refers to the behavior of the cells producing the monoclonal gamma globulin, and not to those of the associated tumor. Sometimes, only after prolonged observation is it possible to ascertain whether a given instance of monoclonal gammopathy is benign or malignant. However, such manifestations as bone lesions or anemia strongly suggest a malignant state.

Benign M-components may belong to any of the known immunoglobulin classes and are immunochemically indistinguishable from similar proteins produced by malignant plasma cell dyscrasias.<sup>261,272,276,297</sup> Benign Bence Jones proteinuria also has been described.<sup>290</sup>

### Incidence

Benign monoclonal hypergammaglobulinemia is a surprisingly common condition and its incidence appears to increase with age. In one study of nearly 7000 sera the incidence was found to be 1% in subjects more than 25 years of age<sup>261</sup> and 3% in those over the age of 70.<sup>274</sup> Others have reported an incidence of 0.1 to 0.3% in healthy blood donors.<sup>272</sup> Thus a large number of individuals,

many apparently normal, carry benign M-components and since the yearly incidence of myeloma is only two to four per 100,000 (Chapter 52), most of these individuals will never develop a malignant plasma cell dyscrasia.

## Etiology

It is obvious from Table 53-2 that benign monoclonal hypergammaglobulinemia occurs under a great number of circumstances which defy unifying concepts of etiology and pathogenesis. Several observations are, however, of interest:

1. It is quite characteristic of BMH that the concentration of the monoclonal protein remains constant over many years.<sup>263,266</sup> Only a small number of such individuals show a very slow and almost imperceptible rise in the concentration of the M-component and eventually develop multiple myeloma or a related plasma cell dyscrasia, often after 10 to 20 years of observation.<sup>279,283</sup> Thus the question remains whether BMH represents a "premyeloma state"<sup>279</sup> and whether all patients with BMH would eventually develop a malignant plasma cell dyscrasia, provided they lived long enough.

2. Since some pathologic M-components appear to have specific antibody activity (page 1605) it is possible that BMH may represent a monoclonal response to antigens encountered during the course of infections or tumor growth. Attempts to establish specificity of benign monoclonal proteins for infectious agents have failed so far,<sup>295</sup> but, in a few instances, tumors were found to be infiltrated with plasma cells containing the patient's own M-component and sometimes M-components could also be identified on the surface of tumor cells.<sup>295</sup> Thus plasma cells infiltrating the tumor may actually be the source of M-components and may represent an immune response against the tumor. In no recorded case, however, has the M-component disappeared after the removal of the tumor,<sup>293,295</sup> with the possible exception of one patient with a benign parathyroid adenoma.<sup>267</sup> It is, of course, equally possible that

**Table 53-2. Conditions That Have Been Associated with Benign Monoclonal Hypergammaglobulinemia**

<b>I Chronic sepsis</b>	
Tuberculosis	<sup>275, 276, 282, 285</sup>
Osteomyelitis	<sup>275</sup>
Pyelonephritis	<sup>285, 295</sup>
Cytomegalovirus infection	<sup>294</sup>
<b>II "Autoimmune" diseases</b>	
Rheumatoid arthritis	<sup>275, 276, 282</sup>
Penarteritis nodosa	<sup>275</sup>
Scleroderma	<sup>282</sup>
Pemphigus	<sup>282</sup>
Necrotizing vasculitis	<sup>295</sup>
<b>III Non-hematologic neoplasms</b>	
Carcinoma of the gastrointestinal tract	<sup>275, 276, 285, 295</sup>
Carcinoma of the biliary tract	<sup>275, 276, 285, 295</sup>
Carcinoma of the liver	<sup>275, 282, 295</sup>
Carcinoma of the breast	<sup>275, 285, 295</sup>
Carcinoma of the ovary	<sup>276</sup>
Carcinoma of the uterus	<sup>275, 282</sup>
Carcinoma of the prostate	<sup>275, 276, 295</sup>
Carcinoma of the bladder	<sup>275, 282</sup>
Carcinoma of the lung	<sup>275, 282</sup>
Malignant melanoma	<sup>275, 295</sup>
Angiosarcoma	<sup>282</sup>
Oligodendroglioma	<sup>273</sup>
Thymoma	<sup>291</sup>
<b>IV Miscellaneous conditions</b>	
Biliary tract disease	<sup>275, 279, 285, 295, 299</sup>
Acute porphyria	<sup>282</sup>
Gaucher's disease	<sup>286</sup>
Hyperlipemia and xanthomatosis	<sup>288</sup>
Sarcoidosis	<sup>273</sup>
Paget's disease of bone	<sup>275</sup>
Hyperparathyroidism	<sup>271</sup>
Parathyroid adenoma	<sup>267</sup>
Pulmonary fibrosis	<sup>297</sup>
Chronic lung disease	<sup>295, 297</sup>
Polyneuropathy	<sup>297</sup>
Pyoderma gangrenosum	<sup>288</sup>

the association of serum M-components and various types of nonreticular neoplasms is a chance event, especially when one considers that the age adjusted rates for malignant disease in this group of patients may be as high as 20%.<sup>295</sup> Alternatively, both may be secondary to a common stimulus, such as an oncogenic virus.

3. Hereditary factors may be of importance since several family members with the same monoclonal macroglobulin have been described.<sup>262,289</sup>

## Clinical Features

The clinical settings in which BMH is found are evident from Table 53-2. While some individuals appear to be completely healthy, others suffer from associated malignant conditions, chronic infections, "auto-immune" diseases, and chronic pulmonary disease, frequently characterized by fibrosis. Occasionally, transient M-components are seen in association with nonmalignant conditions. By definition, *none* of these patients suffers from malignant disease involving the lymphoreticular system and the monoclonal proteins do not contribute to the clinical features of the patient's illness. Skeletal destruction is not seen.

## Laboratory Findings

The peripheral blood reflects the hematologic complications of the associated disease. The bone marrow generally contains fewer than 10% plasma cells and often the number is well within normal limits. The serologic characteristics of the M-components are identical to those of the malignant plasma cell dyscrasias (Chapter 52), but the normal immunoglobulins are not usually decreased. The incidence of Bence Jones proteinuria is low<sup>270</sup> and when present the amount of protein is rather small. As a consequence, renal impairment is rarely present. When present it is usually due to immune complexes involving the M-component.<sup>278</sup>

## Differential Diagnosis

BMH must be differentiated from other plasma cell dyscrasias and this is usually possible on clinical grounds alone. The concentration of the M-component must be measured from time to time. When a plasma cell dyscrasia cannot be demonstrated, a careful search must be made for an associated malignant lesion.

## Prognosis and Therapy

In patients without associated disease the prognosis is quite favorable except in the few,

perhaps 5%, who eventually develop myeloma. Only after a plasma cell dyscrasia has developed should therapy be instituted. Available evidence is insufficient to determine whether or not treatment benefits those with truly benign monoclonal hypergammaglobulinemia, or delays or eliminates the appearance of malignant plasma cell dyscrasias.

## Cryoglobulins (Cryoglobs)

### Definition

Cryoglobulins are serum protein or protein complexes that undergo reversible precipitation at low temperatures.<sup>343</sup> Such proteins were first described by Wintrobe and Buell in 1933<sup>367</sup> and were termed "cryoglobulins" by Lerner and Watson in 1947.<sup>333</sup> Since several serum proteins, including fibrinogen,<sup>325,327,344,354,358</sup> may become cryoprecipitable under appropriate conditions,<sup>321</sup> it is preferable to use the term "cryoimmunoglobulins" (cryoglobs) when describing antibody molecules with this property.

### Immunochemistry

Immunochemically diverse types of cryoglobs occur in a variety of neoplastic, inflammatory, and infectious diseases (Table 53-3) and are readily subdivided into two main categories<sup>321</sup>:

1. About 25% of all cryoprecipitates consist of *monoclonal immunoglobulins* only, usually derived from patients with plasma cell dyscrasias. In multiple myeloma, cold precipitability is usually associated with monoclonal IgG proteins,<sup>321,341</sup> although a few instances of cold precipitable Bence Jones proteins<sup>301,321,334,362</sup> and IgA proteins<sup>302,321</sup> also have been described. In Waldenström's macroglobulinemia, chronic lymphatic leukemia, and non-Hodgkin's lymphoma, the cryoglobulins usually have the characteristics of IgM.<sup>305,306,312,321,337,341</sup> When monoclonal cryoglobs are found in the absence of other discernible disease, patients are said to suffer

**Table 53-3. Cryoimmunoglobulinemia**

<b>I Monoclonal cryoglobs</b>

<b>C Miscellaneous</b>	
	Chronic liver disease <sup>317,343,343</sup>
	Sarcoidosis <sup>341</sup>
	Acute myocardial infarction <sup>318</sup>

from "essential monoclonal cryoglobulinemia." Sera from such patients usually contain IgG cryoglobs.<sup>321,363</sup> The exact relationship of this disorder to multiple myeloma is unclear, although the nature of the protein and the frequent finding of marrow plasmacytosis<sup>316</sup> suggest that this is a plasma cell dyscrasia, perhaps akin to "benign" monoclonal gammopathy (page 1638). Some patients with "essential cryoglobulinemia" eventually develop a malignant plasma cell dyscrasia, usually multiple myeloma.<sup>321</sup>

2. Most cryoglobs (75%) precipitate as immunoglobulin complexes in which one component, usually IgM, but sometimes IgG or IgA, exhibits antibody activity against the second component, which is always an IgG molecule.<sup>321</sup> Such complexes are termed "mixed cryoimmunoglobulins." In about one fifth of these complexes, the anti-immunoglobulin component is a monoclonal protein,

but, in most (four fifths), both components are of polyclonal origin. Occasionally, other proteins such as complement components also form part of the complex.<sup>311</sup> Mixed cryoglobs occur predominantly in association with connective tissue diseases, acute and chronic infections, and a variety of other disorders ("secondary mixed cryoglobs").<sup>321</sup> In such cases, cryoglobs do not possess any antibody activity besides their rheumatoid factor (anti-immunoglobulin) activity,<sup>321</sup> although occasional cases of cryoprecipitable cold agglutinins have been described.<sup>54</sup> Sometimes mixed cryoglobulins containing a monoclonal component are also found in association with plasma cell dyscrasias<sup>321,341</sup> and sometimes they occur in the absence of any discernible underlying disease ("essential mixed cryoglobs").<sup>321</sup>

### Physical and Chemical Characteristics

The physical and chemical characteristics of cryoimmunoglobulins are similar to those of normal immunoglobulins,<sup>321</sup> although the incidence of immunoglobulins and their subclasses and the ratio of  $\kappa$  to  $\lambda$  chains may not follow normal distribution patterns. Thus monoclonal IgM cryoglobs are almost invariably associated with  $\kappa$  light chains and the IgG3 subclass occurs with unusual frequency.<sup>321</sup> Nevertheless, the phenomenon of cryoprecipitation cannot be explained on the basis of unique characteristics of size, shape, or charge. An intact molecule is required for cryoprecipitation since cleavage of interchain disulfide bridges (see Chapter 7) usually results in complete loss of cryoprecipitation activity.<sup>321</sup> It has been suggested that cryoprecipitability is determined by properties resident within the variable region (Chapter 7) of light and/or heavy chains. The mechanisms of cryoprecipitation are unclear but indirect evidence suggests that molecular peculiarities of charge, conformation, and the state of hydration are implicated,<sup>341</sup> and abnormal protein-water interactions appear to be particularly important.<sup>356,357</sup> The interactions are, in general, quite weak and are easily disturbed by mild changes in experi-

mental (in vitro) conditions such as temperature, protein concentration, pH, and ionic strength. Temperature appears to be the most important variable and that at which precipitation starts may range from 35° to 5° C. For any single protein, however, its concentration is also important: in general, the higher the protein concentration, the higher the temperature at which precipitation occurs.<sup>321,341</sup> In addition, the presence of other serum proteins may be a factor in cryoprecipitation, since they apparently help to solubilize cryoIgs.<sup>321</sup> In most cases a pH optimum of 5.5 to 8.0 has been observed and most proteins show decreased solubility with decreasing salt concentrations in the range of 0.05 to 0.3 M.<sup>321</sup> Above 0.3 M, most cryoIgs tend not to precipitate.

## Clinical Features

### Monoclonal CryoIgs

Less than 5% of myeloma proteins and about 7% of Waldenström's macroglobulinemia proteins are cryoprecipitable.<sup>321</sup> Symptoms directly attributable to such proteins are variable and depend at least in part on the temperature and rate at which cryoprecipitation occurs on cooling, a characteristic that is unique for each cryoprotein.<sup>341</sup> The amount of cryoprotein appears to be less important in vivo than in vitro.<sup>341</sup> In one study, two thirds of all patients had no symptoms at all, even in the winter.<sup>341</sup>

Most symptoms result from impaired blood flow due to cryoprecipitation within capillaries.<sup>341</sup> In patients with monoclonal IgM cryoglobulins, the high intrinsic viscosity of these molecules is greatly amplified at lower temperatures and contributes considerably to the poor circulation. Other symptoms of hyperviscosity (page 1626) may also result. The consequences of impaired blood flow are particularly noticeable within the extremities, which may develop cold intolerance, acrocyanosis, tingling, and numbness. Patients may also suffer from livedo reticularis, cutis marmorata, and a typical Raynaud's phenomenon. With time, trophic

changes such as leg ulcers and even gangrene of digits may develop. Dependent purpura is common, but retinal hemorrhages, epistaxis, hemoptysis, and melena may also occur. In addition, thrombosis of major vessels such as pulmonary, renal, and mesenteric arteries has been described.<sup>348</sup> Occasionally, IgM cryoIgs are associated with cold agglutinin activity.<sup>336</sup>

Exposure to cold may also provoke constitutional symptoms such as chills and fever, dyspnea, and diarrhea.<sup>343</sup> Cold urticaria is rarely seen<sup>321</sup> and is associated with complement activation and mast cell degranulation, probably through anaphylatoxin production.<sup>313</sup> Cold urticaria has been transferred passively to normal recipients with whole serum and isolated cryoIgs.<sup>321</sup>

Cryo-Bence Jones proteins usually do not give rise to symptoms and are largely of physicochemical interest.<sup>321</sup>

### Mixed CryoIgs

Two clinical situations, systemic lupus erythematosus and arthralgia-purpura nephritis syndrome, have been most clearly defined.

In *systemic lupus erythematosus*, mixed cryoglobulins are frequently associated with clinically active disease, including renal involvement.<sup>321,321,345,359</sup> These cryoprecipitates most commonly contain IgG, IgM, and the C1q component of complement which is essential for cryoprecipitation, since the latter is abolished by heating for 30 minutes at 56° C. The IgM component is polyclonal and has anti-IgG activity that may be restricted in specificity to the patient's own IgG. Cryoprecipitates containing DNA and IgG anti-DNA antibodies also have been described.<sup>361,319,332</sup> In lupus patients with cryoIgs there appear to be a higher incidence of nephritis and lower complement levels than in those without cryoIgs.<sup>359</sup>

In the *arthralgia-purpura nephritis syndrome*,<sup>321,341</sup> cryoprecipitates containing IgG and IgM, only, have been described. The IgM molecule has rheumatoid factor (anti-IgG) activity and is essential for cryoprecipitation. The IgG can be derived from any

source. One patient with an IgG anti-IgG complex has also been described.<sup>341</sup> Cryoprecipitability is unaffected by heating at 56° C for 30 minutes, although total serum complement activity frequently is low. The clinical manifestations consist of purpura, arthralgia, and weakness in the early stages, and in some patients there is diffuse glomerulonephritis with acute renal failure, frequently with a fatal outcome.<sup>321,341</sup> Both IgG and IgM deposits have been detected in glomeruli in a lumpy-bumpy pattern reminiscent of immune complex disease.<sup>321</sup> There may be hepatosplenomegaly and lymphadenopathy and clinical evidence of autoimmune disorders, such as Sjögren's syndrome and thyroiditis; some patients have antinuclear antibodies.

Mixed cryoIgs also occur in well-defined infections, such as infectious mononucleosis (Chapter 43), in the postperfusion syndrome due to cytomegalovirus infection (Chapter 43), as well as in secondary syphilis, lymphogranuloma venereum, leprosy, kala azar, and other disorders.<sup>321</sup>

## Diagnosis

Proper collection of serum is essential for the detection of cryoIgs, particularly the mixed variety. Blood should be collected in warm syringes and clotted at 37° C. After centrifugation at room temperature or higher, serum is promptly harvested and then stored at 4° C. Monoclonal cryoIgs usually appear within 24 hours or less, but mixed cryoIgs may not appear for several days and a minimal incubation period of 72 hours is essential. When serum is stored in capillary tubes, a cryocrit (volume of cryoIgs/total serum) can be estimated after centrifugation.<sup>321</sup> Finally the isolated cryoglobulin is washed in the cold, redissolved, and subjected to study by immunoelectrophoresis and other immunochemical techniques (see Chapter 7). The cryoprecipitate should be tested for rheumatoid factor activity.

When the concentration of cryoIgs is very high, precipitation or gelling may occur immediately on withdrawal, even when the

syringe is warmed to 37° C. This may be prevented by the use of chelating anticoagulants such as EDTA or ACD.<sup>321</sup> The plasma is then recalcified after its separation from the red cells and the serum is removed at 37° C without significant loss of cryoprecipitate.<sup>321</sup>

Small quantities of cryoglobulins are frequently found in the sera of normal individuals in concentrations of up to 80 µg/ml.<sup>314</sup>

## Therapy

*General measures* such as avoidance of cold cannot be overstressed. Cyproheptadine, an antagonist of histamine and 5-hydroxytryptamine, is useful in the treatment of cold urticaria.<sup>366</sup> In monoclonal cryoimmunoglobulinemias due to *plasma cell dyscrasias*, treatment is primarily directed at the underlying disease. *Plasmapheresis* (page 1629) is of limited benefit, except in monoclonal cryoIgM, in which there is primarily intravascular distribution (Chapter 7). *Corticosteroids* have been effective in a few patients with monoclonal cryoimmunoglobulinemia, presumably because of their anti-inflammatory effects.<sup>322,347,365</sup> Basic organic amines<sup>330</sup> and sulfhydryl compounds<sup>331,353</sup> have been tried but cannot be recommended. The usefulness of cytotoxic drugs such as cyclophosphamide and phenylalanine mustard has not been adequately evaluated, but in isolated instances good results have been achieved, both in essential monoclonal cryoimmunoglobulinemia<sup>307</sup> and in mixed cryoglobulinemia.

### **Complications Due to Metabolic Imbalance**

Hyperuricemia

Hypercalcemia

Serum Proteins

Pregnancy

**T**HE leukemias, lymphomas, myelomas, and related diseases cause morbidity and mortality through three general mechanisms: (1) a deficit in normal cell number or function (eg, infection due to neutropenia or to deficient production of immunoglobulins); (2) invasion of vital organs with impairment of organ function (eg, Hodgkin's disease invading the lung); and (3) systemic disturbance, as manifested by weight loss, pruritus, or metabolic alteration, such as hypercalcemia. The frequency of these complications differs in the various diseases discussed in Chapters 47 through 53. Nevertheless, quite similar complications may be encountered in all of them and for this reason the complications will be discussed here. Treatment may induce ill effects and these must be distinguished from complications associated with the natural course of these diseases. The therapeutic complications are discussed briefly in this chapter, but their expected frequency with various forms of therapy is considered in Chapter 55.

### **Complications Due to Deficient Number or Abnormal Function of Hematopoietic Cells**

Infection, due to neutropenia or immunologic deficiency, hemorrhage, usually due to thrombocytopenia, and anemia are the chief

causes of morbidity in patients with hematologic malignant diseases.

## Fever and Infection

Infection is one of the major causes of death (Table 54-1) in patients with any of the diseases under consideration, and the infections are quite often fulminant. Consequently, the occurrence of fever in a patient with leukemia, lymphoma, or myeloma always raises the question of infection. However, fever can develop as a manifestation of the neoplastic disease in the absence of infection in a patient with any of the diseases under consideration<sup>29, 30, 37, 102</sup> with the probable exception of chronic lymphocytic leukemia (CLL). Additionally, fever may be due to noninfectious complications such as transfusion reaction, splenic infarction, drug toxicity, and thrombophlebitis. Consequently, prompt, careful, and repeated inquiry into the cause of fever is required if intelligent management of the patient is to be maintained.

### Distinguishing between Fever of Infection (FI) and Fever of Neoplastic Disease (FND) without Infection

The likelihood that fever is caused by the disease (FND) rather than by infection (FI) is greater in one disease than another and differs also according to the stage of the disease in question (Fig. 54-1). Thus, chronic lymphocytic leukemia (CLL) is a disease not associated with FND. We have yet to observe fever in a patient with CLL that could not

be explained by infection or by some other complication.<sup>2</sup> In contrast, infection is an uncommon cause of fever in Hodgkin's disease (HD) until the terminal stages are reached or unless exceedingly vigorous therapy has been employed (Chapter 50). Fever in a patient with HD, sometimes of a characteristic type, is a manifestation of the disease itself (Chapter 50) and its presence at the time of diagnosis has been associated with a poor prognosis.<sup>79</sup>

In chronic myelocytic leukemia (CML), fever is uncommon and, indeed, until the late stages, neither FND nor FI is expected unless severe neutropenia has been induced by therapy (Chapter 48). However, the onset of blastic crisis in CML is commonly accompanied by fever (Chapter 48); on the other hand, in the terminal stages of blastic crisis, neutropenia and infection are also frequent.

In either acute lymphoblastic (ALL) or myeloblastic (AML) leukemia, infection is common<sup>102</sup> and so is FND. The same is true of multiple myeloma (MM) and related diseases, and non-Hodgkin's lymphoma (NHL). Thus, in these diseases no assumptions as to the cause of fever should be entertained when the temperature is found to be elevated.

As disease advances, the frequency of infection as a cause of fever increases (Fig. 54-2). This would be anticipated from the considerations in HD and CML, mentioned above, but it is equally applicable to the acute leukemias.<sup>29, 30</sup>

### Evaluation of the Patient with Fever

*Clues to infection as a cause of fever* cannot be found by inspection of the fever curve.<sup>30</sup> Although there is a tendency toward less hectic fever curves and for the pulse rate to be elevated to a lesser degree in FND than in FI, this has no predictive value in the individual patient.<sup>30</sup> In acute leukemia (AL) there is a rough, positive correlation between the severity of neutropenia and the number of neutrophils entering an induced exudate and the frequency of infection.<sup>28, 64</sup> Thus, in a severely neutropenic patient with fever it would be expected that infection was present.

**Table 54-1. Cause of Death in 450 Patients with Leukemia and Lymphoma—Autopsy Studies at the National Cancer Institute, 1965–1971\***

	Percent
Infection alone	69
Infection and hemorrhage	10
Hemorrhage alone	11
Other causes	10

\*Adapted from Levine<sup>74</sup>

Fig 54-1. The frequency of fever due to infection or due to the malignant disease in patients hospitalized at the National Cancer Institute (From Boggs,<sup>29</sup> courtesy of the author and Medical Science.)

The presence of frank, shaking chills is helpful as they are much more common with FI than with FND.<sup>6,30</sup> A careful physical examination is most important, including a rectal examination; *rectal infection* is fairly common in neutropenic patients and often is unsuspected by either patient or physician until an area of tenderness is detected on digital examination.<sup>115</sup> Abdominal tenderness is always alarming since serious infection, often secondary to ulceration of the bowel, may be heralded by this finding.<sup>31</sup> In all instances of unexplained fever, an x ray of the chest should be obtained, even if physical examination or the history fails to indicate pneumonia, because an early infiltrate may be relatively asymptomatic. If a new infiltrate is detected, it is best to assume that it indicates infection (page 1657).

Laboratory examinations that should be made routinely in all febrile patients include culture of blood and urine for bacteria, fungi, and viruses. Septicemia, in the absence of a demonstrable portal of entry (*lanthanic septi-*

Fig 54-2. The frequency of fever during various stages of disease in hospitalized patients with leukemia, lymphoma, or myeloma (From Boggs,<sup>29</sup> courtesy of the author and Medical Science.)

emia), is not unexpected<sup>30,32</sup> and, in neutropenic patients, urinary tract infection may occur without the expected increase in leukocytes in the urinary sediment.<sup>30</sup> Unless there are symptoms suggesting disease of the respiratory or gastrointestinal tracts, routine cultures of pharyngeal secretion, sputum, or stool usually are not helpful.

Unless a specific infection is suggested by the examination or another cause of fever is uncovered by the above-mentioned studies it usually turns out that FND is present. One exception to this suggestion should be stressed. In the patient with lanthanic septicemia the only clue may be the sudden development of general signs of toxicity. The patient who suddenly appears to be quite ill is likely to have septicemia. The development of lanthanic septicemia can be detected with some accuracy if the diagnosis is kept in mind.<sup>29,32</sup> Of 55 patients with fever without an evident focus of infection who were evaluated before the results of blood cultures were known, six were thought to have lanthanic septicemia. Blood cultures proved to be positive in four of these, while positive blood cultures were found in only one of 49 not thought to have septicemia.<sup>32</sup>

The cause of FND is unknown. The presence of fever correlates with the presence of active disease, but it does not reflect the severity of disease with any accuracy<sup>30</sup> (Fig. 54-2). An unidentified substance that produces fever when injected into rabbits was found in the urine of febrile patients with HD, but was not present in normal urine.<sup>124</sup>

#### Management of Fever without Obvious Infection

Antibiotics should not be used simply because fever is present. A controlled clinical trial of tetracycline versus a placebo<sup>32</sup> in FND and a study of the use of ampicillin<sup>45</sup> suggested that routine antibiotic therapy may be harmful because of its role in changing bacterial flora. Thus, if no evidence of infection is detected after careful evaluation and lanthanic septicemia is not suspected, antibiotics should be withheld. However, reevalua-

tion of the febrile patient should be carried out each day. The symptoms induced by FND are quite variable; some patients remain relatively asymptomatic despite the presence of high fever, while others suffer severe prostration. Treating patients with fever by giving aspirin may provide symptomatic relief for some, but in others the sudden temperature drop induced by aspirin with its frequent attendant diaphoresis actually leads to increased morbidity, especially weakness. Indomethacin therapy may lead to fairly long-term control of fever, particularly in patients with HD.<sup>121</sup> Steroid therapy will usually control fever of any cause, at least for a few days,<sup>30</sup> but because of potential side effects this should not be used for fever *per se*.

#### Infection in Neoplastic Diseases of the Hematopoietic System

In managing patients with hematologic neoplasms the accurate diagnosis and treatment of infection can be as important as antitumor therapy (Chapter 55).

#### Defects in Host Resistance Leading to Increased Frequency of Infection

The natural course of the diseases under consideration eventually includes a phase of impaired host defense (Table 54-2). This includes impairment of phagocytic defenses (usually neutropenia), and defective circulating antibody production (humoral immunity) and impaired cellular immunity, or combinations thereof. Antitumor therapy induces similar impairment of the host's defensive mechanisms.

Defects in other aspects of the antimicrobial defense system have been described, but their frequency and overall contribution to the problem of decreased host defense are poorly defined. A reduced rate of phagocytosis of aggregated albumin, carbon, or other particles by the reticuloendothelial system has been reported in some patients with AL, CLL, or MM, but was less common in those with CML or any of the lymphomas.<sup>17,61,92</sup> In one study,<sup>116</sup> antibacterial

**Table 54-2. Usual Causes of Reduced Host Defense during the Natural Course of Neoplastic Diseases of the Hematopoietic System**

Disease	Neutropenia	Defect in Host Resistance	
		Reduced Circulating Antibodies	Impaired Cell Mediated Immunity
Acute myeloblastic leukemia	Common	Rare	Rare
Acute lymphoblastic leukemia	Common	Rare	Rare
Chronic lymphocytic leukemia	Uncommon	Common	Common
Chronic myelocytic leukemia	Rare	Rare	Rare
Blastic crisis of CML	Common	Rare	Rare
Multiple myeloma	Uncommon	Common	Rare
Hodgkin's disease	Rare	Rare	Common
Lymphocytic lymphoma	Uncommon	Common	Common
Histiocytic lymphoma	Rare	Uncommon	Uncommon

activity of native serum was normal for gram-positive bacteria in patients with CLL, CML, or HD, but was abnormally low for gram-negative bacteria. In other studies, normal or increased antibacterial activity of sera was reported in association with all the diseases, but there was disagreement as to which type of disease is characterized by increased activity.<sup>77,112</sup> In monocytic leukemia,<sup>100a</sup> increased bactericidal activity appears to be due to hyperlysozymemia. The role of properdin in antibacterial defenses remains to be clarified<sup>43</sup> and there is disagreement as to whether low<sup>44</sup> or normal<sup>41</sup> levels are found in patients with leukemia, lymphoma, or myeloma. To some extent this discrepancy may reflect differences in methodology since assays involving zymosan or bacteriophage gave different results in the same patients.<sup>14</sup> Activation of the complement system (C1 through C7) is necessary for the full development of inflammation and is crucial to chemotaxis and phagocytosis<sup>106</sup> (Chapter 6). However, since most hereditary abnormalities of the system are not associated with increased susceptibility to infection,<sup>106</sup> measurement of variation in complement levels in some patients with leukemia is of questionable significance.

The expected defect in host defense in each disease is summarized in Table 54-2 and is considered in more detail below.

*Neutropenia* (less than  $1.8 \times 10^9/l$  segmented and band-form neutrophils) is a common complication of AL and low normal neutrophil levels are characteristic of multiple myeloma, but neutropenia is not frequent during untreated phases of other hematologic neoplastic diseases. When neutropenia occurs in patients with HD or NHL, in the absence of suppressive therapy, marrow invasion with tumor or fibrosis of marrow is usually present and anemia and thrombocytopenia are likely to be found in addition to neutropenia. In patients with CML, neutropenia occurs only with blastic crisis, in the face of developing myelofibrosis, or with therapy. Although it has been stated that neutropenia is common in patients with CLL,<sup>44</sup> careful differential counts reveal it to be unusual in untreated patients.<sup>2,120</sup> If, in making the differential count, 500 or 1000 leukocytes are counted, most untreated patients with CLL are found to have normal absolute numbers of neutrophils.

There is some correlation between the degree of neutropenia and the frequency of infection, although it is difficult to define a critical neutrophil level.<sup>2,27,28,30,64</sup> In any of the diseases under consideration, neutropenia is almost always the result of decreased production. When neutropenia is severe, exudates may be devoid of neutrophils,<sup>2,64,66</sup> presumably hindering localization of infec-

tion and explaining the increased frequency of septicemia in such patients.

*Functional defects in neutrophils* (Chapter 42) have also been described in certain circumstances. Some disagreement exists as to whether or not mature neutrophils ingest organisms at a normal rate in patients with CML, but if any defect exists it is minor.<sup>30,121</sup> Phagocytosis is normal in other diseases,<sup>73,122,123</sup> but some defects in killing ingested organisms have been described. Patients with advanced HD and acute leukemia have been reported to have defective candidacidal activity<sup>71</sup> and other bacterial-killing defects have been reported in patients with acute leukemia, especially during chemotherapy.<sup>124</sup> Complete absence of myeloperoxidase was reported in neutrophils from two patients with AML.<sup>47,101</sup> Functionally deficient neutrophils may be found in a number of patients with AML or blastic crisis of CML<sup>42,42a</sup> and defective bactericidal activity by mononuclear phagocytes is common in acute myelomonocytic leukemia, as well as in some patients with lymphoma.<sup>42b</sup> One study suggested that a serum defect might contribute to defective accumulation of neutrophils in exudates in AML subjects.<sup>64</sup> In patients with CML, the total number of neutrophils migrating into induced exudates is normal or even increased.<sup>15</sup>

*Therapy of patients with neutropenia* depends upon the cause of this condition. There is no effective way of stimulating increased neutrophil production. If neutropenia is thought to be due to chemotherapy (Chapter 55), use of the toxic drugs should be discontinued until neutropenia disappears. Conversely, if the neutropenia is thought to be due to the malignant disease, the use of the same drugs may produce a remission of the underlying disease and correct the neutropenia. Leukocyte transfusion is discussed in Chapter 12, and on page 1661.

*Deficient immunoglobulin production* (Chapter 44) is the second major cause of frequent and severe infection in patients with certain neoplastic diseases. Impaired immunoglobulin synthesis in those with CLL frequently is a major cause of infection.<sup>72,76,87,120</sup> A

similar deficit is demonstrable in the majority of patients with MM<sup>53a,76,78</sup> and in a smaller percentage of those with lymphocytic lymphoma.<sup>76,87</sup> Except in severely ill patients, it is unusual in those with other lymphomas<sup>21,87</sup> or HD.<sup>11,76,87</sup> Antibody formation appears to be normal in most patients with acute leukemia<sup>20,51,72,76,104</sup> or with CML<sup>72,76</sup> unless extensive therapy has been employed.<sup>51,62,84</sup>

Defective production of circulating immunoglobulin is often reflected in hypogammaglobulinemia (less than 0.8 g/dl of serum) and by reduction in naturally occurring immunoglobulins such as isoantibodies to red cell antigens.<sup>54,120</sup> If the serum gamma globulin is reduced, defective antibody formation is expected, but the converse is not necessarily true; i.e., defective antibody production may be present in patients with normal levels of gamma globulin.<sup>120</sup> Increased catabolism may also contribute to hypogammaglobulinemia in MM.<sup>121a</sup>

Hypogammaglobulinemia correlates to some degree with duration and severity of disease.<sup>11,120,131</sup> (Fig. 54-3). However, hypogammaglobulinemia may be observed in the absence of extensive CLL or MM and such patients may die of infection at a time when their disease seems to be in a fairly early stage. All classes of immunoglobulins may be depressed or there may be selective depression of one class.<sup>94,104</sup> Normal levels of salivary IgA have been reported in CLL and MM patients in whom serum levels were depressed.<sup>94</sup> Quantitative immunoglobulin levels are normal in most patients with CML,<sup>56</sup> as they are in untreated patients with acute leukemia,<sup>62a</sup> but all classes may be depressed by therapy.<sup>101</sup>

Therapy of defective hypogammaglobulinemia *per se* is quite unsatisfactory. The use of pooled gamma globulin in treating patients with infection is discussed on page 1662. Therapy of MM may lead to improved gamma-globulin levels in a few patients and this has also been noted in HD patients (see Fig. 50-12). However, no improvement in humoral immunity in CLL patients has been reported with any form of therapy.

Fig 54-3. Relationship of the severity of CLL, CML, and HD to serum protein levels. Note that in CLL while levels of gamma globulin decline with increasing severity, other serum proteins do not. Numbers in parentheses are the numbers of observations at each stage of disease. (From Boggs and Fahey,<sup>30a</sup> courtesy of the authors and Journal of the National Cancer Institute.)

*Cell-mediated immunity* is most commonly measured by the patient's ability to react with delayed hypersensitivity to a subcutaneously injected antigen or by lymphocyte conversion *in vitro* in the presence of phytohemagglutinin (PHA). As discussed in Chapter 7, these measures usually correlate with one another and with still other measures. This is usually true in HD; i.e., the patient who is anergic as judged by loss of skin sensitivity to agents such as old tuberculin has lymphocytes that fail to convert when exposed to PHA or to pokeweed mitogen.<sup>42c</sup> However, such correlation is not always present; a normal response to the mixed lymphocyte reaction has been seen in patients whose PHA response was abnormal.<sup>71</sup> The patient with CLL usually shows reduced or absent lymphocyte conversion with PHA,<sup>134</sup> but he does not lose skin hypersensitivity to antigens such as old tuberculin.<sup>120</sup> In spite of this, CLL patients often fail to respond to new antigens such as dinitrochlorobenzene.<sup>83</sup> Patients with HD fail to respond to new antigens and lose prior sensitivity as well.<sup>83</sup>

Thus, in both CLL and HD a defect in cellular immunity is often present, but there

are some differences in the nature of the defect. It appears that patients with HD fail to mount either a primary or a secondary immune response while those with CLL maintain secondary responses, but cannot mount a primary response. Cell-mediated immune responses may be abnormal in NHL or MM patients,<sup>70</sup> but these responses have not been as well characterized as in CLL or HD. Anergy is uncommon in acute leukemia.<sup>51,67</sup>

Various studies differ as to the frequency of impaired cell-mediated immunity. This is due at least in part to differences in the stages of disease studied and the sensitivity of the tests used. In HD there is a direct correlation between the frequency of impaired cell-mediated immunity and the severity and stage of disease (Chapter 50).

Although therapy with a wide variety of antitumor drugs produces anergy as a transient toxic manifestation<sup>12</sup> in either HD or CLL, treatment, if successful, may lead to eventual improvement of cell-mediated immunity.<sup>83</sup> In HD, after apparent eradication of disease by radiotherapy or chemotherapy, cell-mediated immunity as judged by either

skin tests or PHA conversion may return to normal although many months are required in most cases.<sup>83</sup> In CLL, as the blood lymphocyte concentration is reduced by therapy, PHA conversion improves and may revert to normal.<sup>83</sup> Whether this indicates overall improvement in cell-mediated immunity or merely represents the unmasking of a residual population of normally responsive blood lymphocytes remains to be determined.

Splenectomy is now carried out as part of the staging procedure in many patients with HD (Chapter 50). If the hazard of infection is increased by splenectomy, as some hold (see Chapter 45), it does not seem to be increased to a greater degree in HD than in nonmalignant conditions.<sup>49</sup>

### Characteristics of Complicating Infections

The site of infection does not differ appreciably among the various forms of leukemia, lymphoma, and myeloma. Noteworthy in all of these diseases is the frequency with which septicemia may complicate a seemingly trivial infection.<sup>30,113</sup> As judged by one series, the lung is the most common site of serious infection, followed closely by the oral cavity (especially the pharynx), skin,<sup>30</sup> and rectum.<sup>115</sup>

The organisms responsible for infection are quite varied and depend in large part on three factors: recent antibiotic usage, whether the infection was acquired at home or in the hospital, and the nature of the underlying defect in host defense.

It is useful to subdivide infections into three types: *primary infections*, the first infection with a particular organism at a particular site in the absence of antibiotic therapy; *recurrent infections*, developing at the same site or with the same organism after therapy for the primary infection has been discontinued; and *superinfections*, infection that begins while antibiotic therapy is already in use.<sup>30</sup>

Deficiency of humoral immunity most often leads to primary infections with pneumococci, staphylococci, meningococci, *H. influenza*, and sometimes streptococci and

salmonella.<sup>83</sup> Since antibodies are not produced as a result of these infections, recurrent infection with the same organism is common. Unusual causes of infection such as *Pneumocystis carinii* or *Giardia lamblia* may also be primary infecting organisms.<sup>83</sup>

With defective cellular immunity, organisms thought of as "intracellular" pathogens are the common causes of primary infections, namely, the tubercle bacillus, various fungi, and also a variety of viruses as well as salmonella.<sup>83</sup> When combined cellular and humoral defects are present, either intra- or extracellular organisms may predominate.

Organisms associated with primary infection due to neutropenia are similar to those associated with deficiency of humoral antibody except that the gram-negative bacteria, especially *E. coli*, are the organisms that most often are responsible for primary infection.<sup>30</sup> This may reflect infection by flora of the bowel. During hospitalization, patients often become infected with organisms which become part of their flora.<sup>113a</sup> In patients who have recently received antibiotics for FND, primary, recurrent, and superinfections, especially those acquired in the hospital, are more often due to pseudomonas, klebsiella, and proteus.<sup>24,30,38,50</sup> A vicious cycle is established in some patients; the first infection is easily treated; the second is due to a more resistant organism, but is still controlled by vigorous antibiotic therapy; and subsequent infections are caused by organisms against which antibiotics are only partially successful, such as pseudomonas, candida, or aspergillus. This is due, at least in part, to the source of the offending organism. Many and perhaps most patients with leukemia, lymphoma, and myeloma become infected by organisms present in their own normal flora. As the flora, particularly that of the gut, is changed by antibiosis, resistant bacteria and fungi become the predominant species. For practical purposes, the only way in which this cycle can be broken is to induce improvement in host defense, by inducing remission in acute leukemia<sup>102</sup> or by allowing recovery from drug-induced neutropenia. Unfortunately, when reduced circulating immuno-

globulins complicate CLL, NHL, or MM, therapy of the underlying disease may not improve the ability to produce antibodies (page 1654).

Infections with the common bacteria manifest the usual features associated with such infections, with certain exceptions. As previously discussed, septicemia is exceptionally common. Necrotic, ulcerative, and hemorrhagic skin lesions are often noted in pseudomonas septicemia<sup>50</sup> and may be observed occasionally with septicemia due to other organisms in neutropenic patients. In the presence of neutropenia, pus may not appear and blood neutrophil response is absent.

Bacteria that are usually nonpathogenic in the normal population often become pathogens in the compromised host. Thus, *Staphylococcus albus* and nonpigmented *Serratia* are reported causes of infection in a significant number of patients.<sup>24</sup> Clostridial septicemia, an infection usually associated with poorly cared for wounds, may occur de novo in leukemia.<sup>31</sup> The only report of septicemia due to *Corynebacterium equi* was in a patient with NHL.<sup>82a</sup>

*Tuberculous infections*, while uncommon, present a unique problem in diagnosis since the signs and symptoms of tuberculosis are quite similar to those found in the lymphomas; even leukemoid reactions that were due to tuberculosis have been reported (Chapter 41). Reactivation of quiescent tuberculosis may follow loss of cellular immunity due either to disease, especially HD,<sup>83</sup> or therapy. Atypical mycobacteria may also be found to be the cause of infection.<sup>85</sup> At one time, tuberculosis was so frequent in patients with HD that there was strong suspicion that it was the cause of the disease,<sup>4</sup> but, as the frequency of tuberculosis has decreased in the general population, it has become a less common finding in persons with HD.<sup>79</sup>

*Infections with the herpes viruses* are not unusual in patients with depressed cellular immunity and in those receiving steroid therapy. The varicella-zoster virus is particularly troublesome. In 1913, Fieschl reported generalized herpes zoster in a patient with CLL<sup>87</sup> and, in 1924, Pancoast and Pendergrass<sup>93</sup>

called attention to the high incidence of herpes zoster in HD patients. Surveys of large series of patients indicate that infections with the varicella-zoster virus are most common in HD (10% of patients) and occur with increased frequency in NHL and CLL, but in patients with other forms of leukemia or with myeloma they may not greatly exceed the frequency in the general population.<sup>23,119,123,135</sup> Attempts to correlate infiltration of the nerve roots with the presence of localized herpes zoster<sup>23</sup> have been unsuccessful<sup>129</sup>; defective cellular immunity would appear to be the primary fault, particularly when the lesions are disseminated.<sup>68,123</sup> Patients with a prior history of varicella, whether adults or children,<sup>68</sup> may develop local zoster, local zoster followed by varicelliform generalization, or may have a generalized varicelliform eruption initially.<sup>119,123,135</sup> Lesions that remain localized are often very painful, at times becoming superficially gangrenous, and may persist for inordinate lengths of time, but it is the generalized form of the disease that is most serious. Generalized lesions were seen in 14 of 48 instances of herpes varicella infection in adults with HD in one series.<sup>123</sup> Although in that group no deaths were directly attributable to the infection, deaths do occur with such infections.<sup>48,95</sup> Herpes zoster pneumonia, a very rare event, has accompanied generalized herpes in HD.<sup>95</sup>

*Varicella* (chickenpox), the initial manifestation of infection with the varicella-zoster virus, is primarily a disease of children and knowledge concerning this infection in association with hematologic malignant disease is thus limited to ALL. In some patients the course of the disease has not been more severe than in the normal population, but others have developed varicella pneumonia, which occasionally has proved fatal.<sup>25,96</sup> Some of the patients developing this complication were receiving steroids—therapy known to be associated with varicella pneumonia in nonleukemic populations<sup>96,103</sup>—and almost all had been receiving some form of antileukemic therapy.<sup>25,96</sup> Therefore, it is uncertain whether varicella infection when

severe is due to the existence of the underlying disease, to therapy, or to both.

*Herpes simplex* infections are common, particularly in febrile patients, but whether they are more common in leukemia and lymphoma than in other diseases of which fever is a manifestation is uncertain.<sup>91</sup> Severe, spreading simplex infections are observed occasionally and may be varicelliform in character and grossly indistinguishable from zoster (Fig. 54-4). In our experience, severe spreading herpes simplex infections have occurred only in patients receiving steroid therapy.

Severe complications may follow *vaccination for smallpox*, particularly in patients with CLL. Generalized vaccinia,<sup>92 130</sup> or a severe spreading local reaction, vaccinia gangrenosum, may occur<sup>55</sup> and often is fatal. Poor circulating antibody response may be the

primary cause of this reaction since these complications also have been reported in patients with hypogammaglobulinemia due to other causes.<sup>46,55,83</sup> Patients with other forms of leukemia who developed these lesions had been receiving antileukemia therapy.<sup>46</sup> The presence of any form of hematologic neoplasm should be considered a contraindication to smallpox vaccination.

Symptomatic *cytomegalovirus infection* is fairly common in patients with acute leukemia subjected to vigorous therapy, but is much less common in those treated in a less intense fashion<sup>53,105,120</sup>; it is a problem in anergic patients with HD.<sup>81</sup> Localized self-limited infections with this virus occur in most persons. Consequently, isolation of the virus from a single source, such as the urine,<sup>13,106</sup> or serologic evidence of infec-

Fig 54-4 Disseminated herpes simplex lesions in a patient with HO (From Muller et al<sup>91</sup> courtesy of the authors and American Journal of Medicine)

tion<sup>126</sup> does not necessarily indicate serious infection. Generalized infection, associated with evidence of pneumonia, may prove fatal and in such patients the virus can be found in many sites such as sputum, blood, urine, and CSF.<sup>105</sup>

Other viral infections of serious nature rarely occur although occasional reports of such severe complications as fatal pneumonia due to natural measles infection or to measles vaccine have appeared.<sup>89</sup> Reports of such infections as lymphogranuloma venereum in patients with CLL<sup>80</sup> are of interest, but an increased frequency of such infection has not been established.

In most instances of infection with opportunistic fungi these organisms are found as pathogens in the setting of depressed host

defense, advanced disease, chemotherapy, and heavy antibiotic usage. For instance, oral moniliasis (Fig. 54-5) occurring in terminally ill patients was shown to be most common in patients receiving antibiotics, antitumor therapy, and steroids; next most common in patients in whom two such factors were present; and least common when only one factor was present.<sup>33</sup> *Torulosis glabrata* has been reported as a pathogen in only 11 patients, but all of these had severe, underlying illness and all but one were receiving antibiotics, steroids, immunosuppressive chemotherapy, or combinations thereof.<sup>82</sup> Evidence has been presented that antibiotics enhance the incidence of candida by altering the fungus and perhaps by changing host resistance as well as altering normal flora.<sup>114</sup>

Fig 54-5. Oral moniliasis of lips (A), gingiva (B), hard palate (C), and "bite line" (D) in patients with acute leukemia

*Candida species* probably are the most common cause of serious fungal infections, followed closely if not exceeded by *aspergillus*,<sup>19,86,89</sup> but a variety of other fungi also have been reported.<sup>101,111,136</sup> Proof of infection with these organisms is often quite difficult to obtain because cultural evidence of the presence of fungi in the pharynx, sputum, or stool does not constitute evidence of infection, these organisms often being part of the normal flora.<sup>18,33,101</sup> Furthermore, abscesses attributable to these fungi are often quite difficult to detect.<sup>97,101,136</sup> In one series of 49 patients with acute leukemia, eight had systemic fungal infections at autopsy; in only one of these was the infection detected during life.<sup>48</sup> In another series, 18 of 65 patients had fungal infection at autopsy, but in none of these had the infection been diagnosed during life.<sup>83</sup> Demonstration of budding forms or of pseudomycelia on gram stain constitutes good evidence of significant infection, as does tissue invasion noted in biopsy specimens.<sup>33</sup> The presence in serum of precipitating antibodies against the cytoplasmic "S" antigen of *C. albicans* suggests visceral infection with that organism. However, demonstration of agglutinating antibodies and positive reactions to skin tests are of little diagnostic value unless rising antibody titers are observed since there is a high frequency of positive reactions in the general population.<sup>97,100</sup> Serum levels of antibody against aspergillosis have not proved useful in detecting invasive disease.<sup>139</sup> The detection of cryptococcal antigen in CSF may be useful in diagnosis of infection due to this agent.<sup>59</sup>

By routinely culturing bone marrow aspirates for fungi from patients with leukemia, six otherwise unsuspected systemic infections were uncovered in 187 patients, namely, histoplasma, cryptococcus, and candida.<sup>65</sup>

Most reports of such unusual infections as torulosis have been recorded in patients with HD or CLL.<sup>39,52</sup>

Other types of parasitic infection that are common but usually are asymptomatic in the general population may be serious in patients with depressed host defense, eg, toxoplasmosis.<sup>16,40,81,109,173</sup> *Pneumocystis carinii* infec-

tion also may occur and may be difficult to recognize<sup>107,110</sup> unless techniques such as endobronchial brushing are employed.<sup>104a</sup>

Simultaneous infection with more than one organism is common.<sup>24,30</sup>

### Treatment of Infections

The most critical steps in therapy are isolation of the specific organism, determining its sensitivity to antibiotics, and attempting to improve the underlying defect in host defense. Antibiotic therapy should be as specific as possible, not only to properly combat the infecting organism, but also to change residual host flora as little as possible. Thus, in pneumococcal infection, modest doses of penicillin are preferable to the use of broad-spectrum antibiotics. Since superinfection is common<sup>39</sup> the blood and material from infected sites must be recultured repeatedly in patients who are not responding to therapy in the expected manner. Broad-spectrum antibiotic coverage is necessary in certain circumstances, as in the patient with suspected septicemia in whom results of blood cultures are not yet available. In such a patient, one of the penicillinase-resistant penicillins such as cephalosporin or ampicillin should be coupled with one of the agents possessing broad activity against gram-negative organisms such as gentamycin, colistin, or kanamycin. If the setting is such that pseudomonas infection is likely, large doses of carbenicillin should be added as well.

Patients having systemic fungal infection are usually treated with amphotericin,<sup>19</sup> although those with some strains of candida or cryptococcus may be treated with 5-fluorocytosine,<sup>128</sup> an apparently less toxic drug than amphotericin. Nystatin, applied locally, is of benefit in treating patients with superficial infections such as thrush,<sup>33</sup> but is of no benefit in those with systemic infections since it is not absorbed.

Treatment of patients with viral infections generally is unsatisfactory. Patients with the herpes viruses and complications of smallpox vaccinations may be treated by administering large doses of hyperimmune gamma globu-

lin.<sup>55</sup> Thiosemicarbazones may be useful in disseminated vaccinia.<sup>35</sup> The administration of transfer factor (Chapter 44) holds some promise of correcting failure of antibody formation and has been used with apparent benefit in disseminated vaccinia.<sup>83</sup> No treatment of proven benefit has been reported for cytomegalovirus infection.

Pentamidine is useful in treating patients with severe infections with *Pneumocystis carinii*<sup>732</sup> and pyrimethamine and sulfonamides have been reported to be useful in that infection,<sup>110</sup> as they have in toxoplasmosis.<sup>16</sup>

*Gamma globulin therapy* for acute infections may be tried in patients with deficient circulating immunoglobulins. It is of no benefit in infected, neutropenic acute leukemics<sup>20</sup> since immunoglobulin defenses are usually intact in this disease (page 1654). Whether gamma globulin has any influence on infection in patients with CLL or MM remains to be determined.

*Neutrophil transfusion*, properly performed, is probably of benefit to the infected, neutropenic patient.<sup>24,34,58,74</sup> However, as reviewed in Chapter 12, this experimental procedure is fraught with difficulties. Simply collecting enough neutrophils to give a meaningful dose is difficult and the life span of this cell in normal subjects is so short that daily transfusions would be necessary to more than transiently raise the level of neutrophils.<sup>34</sup> Neutrophils are quite susceptible to in vitro damage so that the majority of infused cells fail to circulate in the recipient unless they have been collected appropriately. Incompatibility of HLA haplotype and naturally occurring or acquired leukoagglutinins are other factors that may make such transfusions ineffective.<sup>58,69</sup> Adverse reactions to leukocyte transfusion may occur, as they do with transfusion of any other blood product (Chapter 12). Transfused lymphocytes have survived for sufficient periods to produce graft-versus-host disease in immunosuppressed patients.<sup>60</sup> When CML leukocytes have been infused, transient engraftment of Ph<sup>1</sup> chromosome-containing cells has been noted in the marrow of patients with AL, but no permanent "takes" of CML have been ob-

served.<sup>60</sup> Toxoplasmosis has been transmitted by neutrophil transfusion.<sup>69,117</sup> For the present, neutrophil transfusion must remain an interesting, but experimental, form of therapy.

### *Prevention of Infection*

A variety of means have been sought to reduce the frequency of infections during periods of defective host resistance.

*Antibiotics given prophylactically* are of proved benefit in conditions in which one is trying to prevent infection with a specific organism, such as prophylaxis for streptococci in patients who have suffered from acute rheumatic fever or for shigella during epidemics of dysentery. However, prophylactic antibiotics are of no proven benefit in avoiding infections from a wide variety of organisms. Indeed, by changing the flora of the host they may well be harmful.<sup>32</sup> The ideal goal of prophylaxis, complete sterilization of the patient, is virtually impossible to achieve unless a "sterile environment" is also provided. However, gut sterilization can be attained in some patients treated in normal hospital environments with a combination of oral, nonabsorbable antibiotics.<sup>99</sup>

"Sterile" environments consist of units such as "life-island" or laminar flow rooms.<sup>24</sup> The laminar flow room is one in which air, sterilized by filtration, flows uniformly from one end of the room, usually from the head of the bed, to the other. The patient's bed, nightstand, etc. are sterilized, but the end of the room toward which air flows is nonsterile. An attempt is made to render the patient germ-free by intense scrubbing of the skin supplemented by the topical application of antibiotics and large doses of oral, non-absorbable antibiotics, and by feeding him sterilized food and water. In some instances, no organisms have been cultured from patients maintained in this manner and the frequency of infection has been reduced as compared to that in patients maintained in a normal hospital environment.<sup>24,135a</sup>

The psychological difficulties associated with this type of isolation may be considerable and the cost of maintaining patients in such an

environment is high. Thus, until it is shown that the maneuver leads to overall benefit, such as a much greater frequency and duration of remissions in AML patients, it should be considered a form of experimental therapy. In this regard, in a controlled trial the frequency and severity of infection were reduced in adults with newly diagnosed acute leukemia who were maintained in a protected environment ("life-island" or laminar flow room) and sterilized with antibiotics to the extent possible, as compared with (1) those having sterilization of the gut without utilizing a protected environment, or (2) those having neither prophylactic antibiotics nor a protected environment.<sup>75</sup> No difference was observed between the patients of the two latter groups. However, neither the frequency nor the duration of remission differed between the groups. "Sterile" environment units may be helpful in ensuring survival during experimental therapeutic procedures such as the administration of lethal doses of irradiation with the object of salvage by bone marrow transplantation (Chapter 55).

*Prophylactic administration of gamma globulin* to patients with reduced serum immunoglobulins due to CLL, NHL, or MM has not been studied in a consistent enough fashion to evaluate.<sup>41</sup> Very large, frequent doses would be required to maintain normal levels in such patients. This would be attended by a significant frequency of allergic reactions as well as hepatitis. However, in such patients who are suffering from severe, recurrent infections a trial of prophylactic gamma globulin therapy would appear to be justified.<sup>47</sup>

*Antituberculous prophylaxis* with isoniazid should be used in any patient with a history of tuberculosis since reactivation may occur due to the underlying disease or to therapy. Such therapy also is advisable if the reaction to the tuberculin skin test is positive, particularly if steroid therapy is used.

## Homorrhage

Serious, life-threatening hemorrhage is a common problem in the acute leukemias and may occur in association with any of the

diseases under consideration. It is usually the result of thrombocytopenia, but may be secondary to platelet dysfunction, disseminated intravascular coagulation (DIC), liver disease, the hyperviscosity syndrome, or still other causes.

## Thrombocytopenia

Reduced numbers of platelets are found in more than 90% of patients with acute leukemia at the time of diagnosis, and modest reductions are observed in a significant number of patients with CLL and MM.<sup>1,2,9</sup> Thrombocytopenia is unusual in untreated patients with lymphoma, unless marrow invasion or marrow fibrosis is present, and when noted in patients with CML it usually indicates impending or overt blastic crisis. However, thrombocytopenia is a common side effect of chemo- and radiotherapy in any of these diseases.

Petechiae and ecchymoses are the most common manifestations and may occur with only modest degrees of thrombocytopenia (Fig. 54-6) (Chapter 34). Life-threatening hemorrhage from thrombocytopenia is usually associated with very severe platelet reduction. Such hemorrhage usually is into the gut or the subarachnoid space, but pulmonary hemorrhage, uterine hemorrhage, and hemorrhage from unusual sites such as the ovary<sup>159</sup> also may cause death.<sup>1</sup> Epistaxis, while troublesome, usually can be controlled by local measures and, while hematuria is fairly common, it is rarely life-threatening.

The relationship of hemorrhage to the degree of thrombocytopenia has been defined in acute leukemia<sup>151</sup> (Fig. 54-6). Ecchymoses and petechiae were found occasionally when platelet counts were above  $50 \times 10^9/l$  and became increasingly more frequent as more severe degrees of thrombocytopenia were encountered. Life-threatening hemorrhage was not observed when platelet counts were above  $50 \times 10^9/l$  and indeed was in no sense common until less than  $5 \times 10^9$  platelets/l were present. Thus, if serious hemorrhage occurs with platelet counts exceeding 20 to  $30 \times 10^9/l$ , other causes contributing to hemorrhage should be searched for.<sup>150</sup>

Fig 54-6 Relation between hemorrhage and platelet count. The percentage of days when hemorrhage occurred in the 92 patients combined is shown for each of the levels of platelet count. Curve I shows data for all hemorrhagic manifestations. In curve II skin hemorrhage and epistaxis have been excluded. Curve III refers only to grossly visible hemorrhage. (From Gaydos,<sup>111</sup> courtesy of the author and New England Journal of Medicine.)

In acute leukemia or when thrombocytopenia is induced by chemotherapy, decreased platelet production almost always is responsible for the reduction in blood platelets. Examination of bone marrow from such patients reveals decreased numbers of megakaryocytes. Some shortening of platelet survival may also contribute to thrombocytopenia.<sup>145a</sup>

Decreased production and shortened intravascular survival both contribute to thrombocytopenia in patients with advanced HD.<sup>137</sup> and reduced survival has been found at diagnosis, even in the absence of thrombocytopenia.<sup>138</sup> Increased platelet destruction, presumably as a result of formation of platelet autoantibodies, is a cause of thrombocytopenia in an occasional patient with CLL.<sup>2,117</sup> In this instance, abundant megakaryocytes are present in the bone marrow in the face of severe thrombocytopenia, and platelet survival is markedly shortened. We have observed a similar picture in a patient with MM and it has been reported in patients with HD.<sup>6</sup> Platelet pooling in an enlarged spleen has been demonstrated as a contributing cause of thrombocytopenia in a few patients.<sup>137</sup> An average of 70% of platelets were

in the spleen in one series of patients with HD, even though thrombocytopenia was not present.<sup>138</sup>

*Therapy of thrombocytopenic bleeding depends, in part, upon the cause of the thrombocytopenia. If severe bleeding develops, prompt and vigorous use of platelet transfusion is indicated.*<sup>146,156,174,175</sup> The usefulness of platelet transfusion in the treatment of thrombocytopenic hemorrhage was demonstrated in a comparative study of the transfusion of fresh versus stored blood.<sup>149</sup> Transfusion of platelet substitutes or of nonviable platelets was proved to be ineffective.<sup>145</sup> Transfusion of freshly prepared platelet concentrates is the therapy of choice.

Techniques for obtaining, storing, and transfusing isologous platelets were discussed in Chapter 12. With hemorrhage, the platelets from at least 8 units of blood should be given to an adult and those from at least 4 units to a child. No upper limit for the number of platelet transfusions can be stated since vigorous administration should be continued until bleeding has been interrupted.

If the picture is compatible with increased platelet destruction, a situation seen most often in CLL, as mentioned above, therapy

with adrenal steroids is recommended. Initially at least 1 mg/kg of prednisone or its equivalent should be given. If platelet destruction is not interrupted by steroids or if large doses must be used over a prolonged period, eg, more than 10 mg/day of prednisone for more than six months, splenectomy should be considered.

The only effective long-term treatment for thrombocytopenia secondary to decreased platelet production is to induce significant improvement in the underlying disease or to discontinue antitumor therapy if that is thought to be the cause. Thrombocytopenia remits as remission is induced in acute leukemia<sup>1</sup> or if marrow function is improved by therapy in other diseases such as HD.<sup>161</sup>

*Prophylactic platelet transfusions* for severely thrombocytopenic patients with neoplastic disease are commonly used. Their effect in reducing the frequency of death due to hemorrhage seems unquestioned (Chapter 47, Table 47-4). However, in many instances the cost is prohibitive. Platelet transfusion commonly fails in two circumstances: in the febrile infected patient and in the patient who develops isoantibodies to platelets.<sup>174,178</sup> In both circumstances, platelet utilization is so brisk that increased counts cannot be maintained by transfusion.

Since the risk of fatal hemorrhage is minimal with a platelet count above  $20 \times 10^9/l$  (Fig. 54-6), this value is often used as the minimal desirable one in a prophylactic transfusion program. In the absence of infection, transfusion twice a week with the platelets from 6 to 8 units of blood usually will keep the platelet count above  $20 \times 10^9/l$ . However, isoantibodies often develop within a few weeks<sup>175,176a</sup> unless a single donor, preferably an HLA-compatible sibling or an unrelated but HLA-compatible donor,<sup>179</sup> is utilized. The development of isoantibodies is evidenced initially by failure to raise the platelet count by transfusion, an event that can also reflect incorrect processing of the platelets (Chapter 12). Thus, failure to increase the count on more than one occasion should be documented before assuming that isoantibodies have developed.

A prophylactic transfusion program is difficult to justify in all severely thrombocytopenic patients with neoplastic disease. In the patient in whom an improved platelet level can be anticipated following therapy, or when thrombocytopenia is the result of therapy and therefore the condition is expected to improve shortly, such a program has potential value. One alternative to the prophylactic use of platelets is to employ platelet transfusions to interrupt bleeding once it has begun. The difficulty with this approach is that subarachnoid hemorrhage is a common cause of death from thrombocytopenia, especially in AML patients,<sup>1</sup> and transfusion, once subarachnoid bleeding begins, is rarely of benefit. Secondly, interruption of severe hemorrhage may require more platelets than are immediately available since they are rapidly utilized until bleeding has been interrupted. Thus, we prefer a prophylactic transfusion program for patients in whom there is reasonable expectation for improved platelet production within a few weeks. However, if such expectation is unrealistic, as in the patient with AML who has failed to respond or is no longer responsive to useful forms of therapy, prophylactic platelet transfusion is likely to be futile. It may change the cause of death, but will not prolong useful life to any significant degree.

### Disseminated Intravascular Coagulation

Disseminated intravascular coagulation (DIC) (Chapter 38), with significant hemorrhage, may occur during infection, especially with gram-negative sepsis.<sup>149</sup> In addition, a DIC-like syndrome complicates certain cases of acute promyelocytic leukemia and, rarely, other forms of AL in the absence of infection.<sup>178</sup> Surveys of leukemia populations reveal modest decreases in fibrinogen in the absence of hemorrhage in some patients.<sup>153,177</sup> Although this pattern was thought initially to be the result of increased fibrinolysis, fibrinolysis as such usually cannot be documented and it appears more likely that most, if not all, cases represent instances of DIC.<sup>179,148,153,158,162,171</sup> However, modest

degrees of fibrinolysis may contribute to thrombocytopenic hemorrhage in the absence of DIC in occasional leukemic patients<sup>167</sup> and high levels of fibrinolysins have been noted in patients with CLL.<sup>141,168</sup>

*Promyelocytic leukemia* is often associated with bleeding. Then hypofibrinogenemia as well as thrombocytopenia and often reduction of other clotting factors are seen. This pattern is encountered on rare occasions in patients with acute monocytic,<sup>1,142,162</sup> myeloblastic,<sup>164</sup> or lymphoblastic leukemia<sup>148</sup> and even in NHL.<sup>166</sup> In these patients, very large, rapidly spreading ecchymoses are found. In the typical patient with this syndrome the promyelocytes are characterized by numerous, abnormally large, eosinophilic-staining granules and often some basophilic granules and other crystalline inclusions are present as well.<sup>143,173,176</sup> Large amounts of thromboplastic activity in extracts from such cells have been demonstrated in vitro, suggesting that DIC may be triggered by a product of the leukemic cell.<sup>142,163,170</sup>

Therapy of patients with this form of bleeding, as of those with most complications of acute leukemia, is of transient benefit unless the underlying disease can be modified. Although certain authors have suggested that induction of remission in such patients is quite difficult,<sup>143</sup> we have observed the same rate of remission as with other forms of AML.<sup>140</sup> The use of fibrinogen or of antifibrinolytic agents has been of questionable value.<sup>2,139,148,153,171</sup> A reasonable approach to the treatment of the patient with AL who has severe DIC as part of his initial picture is to institute intensive antileukemic therapy with the object of reducing the total number of leukemic cells as quickly as possible, since these are the presumed inciting cause of the DIC. If infection is present, intensive therapy for this complication should also be instituted promptly. Heparin should probably be given as well,<sup>153a</sup> and if severe thrombocytopenia and/or hypofibrinogenemia are present, replacement therapy should be given as heparin is administered.

*Vascular lesions* reminiscent of those seen in thrombotic thrombocytopenic purpura

(Chapter 34) have been observed in patients with acute leukemia and in patients with CML.<sup>160</sup> Whether these are simply the vascular lesions of DIC or are distinct will require further study.

*Thrombocytopathic hemorrhage* is observed in some patients with CML and AML<sup>144,145a</sup> as well as in patients with polycythemia vera (Chapter 30), myelofibrosis or idiopathic thrombocythemia (Chapter 57). As discussed in Chapter 57, this seeming paradox of bleeding in the presence of excessive numbers of platelets<sup>155</sup> is thought to be due to functional defects of platelets. Evidence for functionally deficient platelets has been presented in occasional patients with acute leukemia.<sup>145a,168</sup>

### Other Causes of Hemorrhage

*Liver disease* may result in hemorrhage, because of reduction in factors II, V, VII, IX, and X as well as other defects (Chapter 38). While significant liver disease may be the result of tumor infiltration in any of these conditions, it is more often due to complicating factors such as viral hepatitis or hepatotoxicity from antitumor therapy (Chapter 55). In two patients with acute leukemia, isolated and unexplained severe deficiency of factor V and of factor X, respectively, were considered to be the cause of hemorrhage.<sup>152</sup> In another case, a circulating anticoagulant, apparently produced by leukocytes, was thought to be the cause of hemorrhage in a patient with AML.<sup>156</sup> We have also observed circulating anticoagulants of unknown sources in a patient with MM. Patients with paraproteins in high concentration may have hemorrhagic manifestations due to the hyperviscosity syndrome (Chapter 52). Chronic subdural hematoma, perhaps secondary to meningeal leukemia, has been observed in ALL.<sup>168a</sup>

### Abnormalities of Erythrocytes

#### Anemia

Anemia is found in all of the hematologic malignant diseases (Chapters 46-53) and in

some, such as the acute leukemias and myeloma, it is such a common part of the clinical picture that one must be particularly cautious in making a diagnosis in its absence. Anemia is responsible for some of the complaints of *fatigue* and a *vague sense of ill health*. In general, the presence and severity of anemia usually reflect the severity of the disease.

The anemia is most often normochromic and normocytic, although in certain circumstances it may be macrocytic or marked anisocytosis and poikilocytosis may be present. The primary mechanism of anemia, in most instances, is *decreased production of red cells*, reflected in decreased reticulocytes and decreased nucleated red cells in the bone marrow. Iron kinetic studies indicate erythroid hypoplasia.<sup>219,221</sup>

The cause of the decreased red cell production is unknown. It is often attributed to replacement of the marrow by tumor, but there are reasons for thinking that simple mechanical displacement of erythroblasts by tumor cells or competition for nutrients cannot explain decreased production in most patients. Many patients with lymphoma are anemic, but do not have demonstrable invasion of the marrow. In the leukemias, when marrow invasion is present, there is little or no correlation between the degree of anemia, thrombocytopenia, and neutropenia.<sup>1</sup> If "crowding out" were the primary problem, all normal cells would be expected to be equally affected. As in the anemias of chronic disorders (Chapter 18), transferrin levels tend to be decreased in most patients with hematologic malignant disease and serum iron levels are often low in those with CLL or MM.<sup>192,199,221</sup> On the other hand, serum iron levels usually are normal or elevated in AL and CML patients<sup>185</sup> and may be high, normal, or low in those with the lymphomas.<sup>219</sup> Thus, a high percentage of transferrin is saturated in many patients, and in this way the anemia differs from that of certain other chronic disorders (Chapter 18).

Erythropoiesis usually is under the control of erythropoietin in the leukemias and lymphomas,<sup>190,221</sup> even when the presumably malignant erythropoiesis of DiGuglielmo's

syndrome is present.<sup>198,201,215</sup> Erythropoietin levels are usually, but not invariably, increased to a degree appropriate to the degree of anemia.<sup>201</sup> Transfusion to a normal level of erythrocytes appropriately reduces the rate of red cell production to a degree corresponding to decreasing erythropoietin production. Interestingly, however, in two patients with CML in whom an erythroblastic crisis occurred, erythropoiesis that was autonomous of erythropoietin was noted.<sup>215</sup>

*Hemolytic anemia* of severe degree, associated with a positive reaction to Coombs' test, complicates the course of from 10 to 20% of patients with CLL and occurs in some patients with HD and NHL and occasionally in those with MM. Autoimmune hemolytic anemia may antedate the appearance of CLL, NHL, or HD by months<sup>218</sup> or years.<sup>191,202</sup> An episode of idiopathic autoimmune hemolytic anemia may be the first sign of leukemia or lymphoma. Severe hemolysis has been reported in a few CML and AML patients. In such subjects, while a positive Coombs' reaction has been noted,<sup>206</sup> the reaction more often has been negative.<sup>192,197</sup> In CLL there is no apparent relationship between the development of hemolysis and the severity or duration of the disease.<sup>2</sup> The antibody usually is more active in the warm than in the cold. Severe hemolysis as a primary cause of anemia probably does not occur in more than 3% of patients with HD.<sup>193</sup> Most of these patients have had fairly widespread disease but no special features predisposing to development of autoimmune hemolysis were detected and the hemolysis did not seem necessarily to be a bad prognostic sign.<sup>195,209</sup> As with CLL, the antibody usually is warm reacting and cold agglutinins usually are absent.<sup>195</sup> Thrombocytopenia, possibly of autoimmune nature, may be present as well.<sup>195</sup> The onset is often quite sudden and hemolysis can be exceedingly severe, so much so that death from cardiac failure has occurred before transfusions could be given.<sup>1,184</sup>

The diagnosis is established by the same studies that detect any form of hemolysis (Chapter 20), the indirect fraction of serum bilirubin usually is elevated, and excretion of

urobilinogen in urine and feces is abnormally high. Often there is an appropriate marrow response reflected in increased blood reticulocytes, but this may be absent, particularly if the patient is receiving cytotoxic chemotherapy when hemolysis begins.

Less severe hemolysis, reflected only in a modest decrease in red cell survival without reticulocytosis or hyperbilirubinemia, may occur.<sup>192,203,208,217</sup> When red cell survival is shortened in the leukemias, lymphomas, or myeloma, the reduction is modest, rarely exceeding a two-fold decrease unless autoimmune hemolytic anemia is present.<sup>203,221</sup> Sequestration of erythrocytes with or without increased red cell destruction in large spleens may contribute to the anemia.<sup>187</sup>

A degree of *ineffective erythropoiesis* is found in some patients, most strikingly in those with DiGuglielmo's syndrome, as determined by percent incorporation of <sup>59</sup>Fe into circulating red cells or by a discrepancy between plasma iron turnover and reticulocyte numbers,<sup>193,201,215</sup> but iron utilization appears to be normal in most patients with HD or NHL.<sup>199</sup>

*Macrocytic anemia with marrow cells resembling megaloblasts* is noted in patients with DiGuglielmo's syndrome and sometimes is found in other patients with AML in whom the predominant cell is a myeloblast rather than the proerythroblast of DiGuglielmo's syndrome. Megaloblastosis may result from the use of any of the antitumor agents whose primary effect is inhibition of DNA synthesis (Chapter 55), such as the folic acid antagonists, cytosine arabinoside, 6-mercaptopurine, and procarbazine. However, the abnormal nucleated red cells that may appear in AML in the absence of such drugs or occur as part of the terminal phase of CML or even polycythemia vera (Chapter 30) or myelofibrosis (Chapter 57) have certain morphologic features that often allow their differentiation from megaloblasts due to deficiency of B<sub>12</sub> or folic acid. Thus, the nuclear chromatin is not as fine as in true megaloblasts and a greater proportion of the erythroid precursors are more immature in most patients with DiGuglielmo's syndrome than in

those with B<sub>12</sub> or folate deficiency. Furthermore, in many patients with DiGuglielmo's syndrome, bi- and even tri-nucleated erythroblasts are much more numerous than in patients with B<sub>12</sub> and folate deficiency. In addition, the changes in neutrophils characteristic of those vitamin deficiencies, such as hypersegmentation, giant metamyelocytes, and macropolycytes, are usually absent.

*Nucleated red blood cells (NRBC)* are found easily in blood smears of most patients with DiGuglielmo's syndrome and may be more frequent than leukocytes. They may be found on blood smears of patients with other morphologic types of AML, but they are fewer in patients with ALL.<sup>1</sup> In CML, NRBC are found in blood smears but they are rarely as frequent as in myelofibrosis (Chapter 57). In CLL and in MM their presence usually indicates complicating factors such as hemorrhage or hemolytic anemia. Marrow invasion or myelofibrosis associated with HD or NHL often is associated with the presence of NRBC on blood smears.

*Therapy for the usual anemia* that is present in leukemia, lymphoma, and myeloma patients may be difficult. Transfusions should be used when required for control of symptoms and signs due to the anemia (Chapter 13). Appropriate studies may be indicated to rule out the possibility of deficiency of iron, B<sub>12</sub>, or folic acid as a cause of the anemia, but therapy with these agents as a routine procedure is of no benefit. In many cases, if the underlying disease can be alleviated by specific therapy, the anemia will be corrected or at least lessened. Thus, induction of remission or significant improvement in patients with acute leukemia, CML, the lymphomas, or myeloma leads to improved red cell production. However, this is not always the case in those with CLL.<sup>2</sup> Large doses of synthetic androgens are occasionally helpful in treating the anemia, as they are in treating aplastic anemia (Chapter 56). Steroids or splenectomy may lead to reduction in anemia in patients with CLL, even in the absence of overt hemolysis.<sup>2,187</sup>

*Therapy of autoimmune hemolytic anemia* consists primarily of transfusion, steroid ad-

ministration, and, in certain subjects, splenectomy, as discussed in Chapter 27. Prednisone, 40 to 60 mg/day, or other adrenal corticosteroid hormones in equivalent dosage, will interrupt or at least reduce the degree of hemolysis in most patients.<sup>2,195</sup> Use of the drug should be continued at full doses until all evidence of hemolysis has disappeared and the hematocrit has returned to prehemolysis levels. The dosage is then diminished gradually. In some patients, hemolysis does not recur as steroid administration is tapered and stopped. In most but not all patients in whom hemolysis recurs or in whom steroids failed to interrupt hemolysis, splenectomy controls the hemolytic process. If the patient is in otherwise relatively good condition, the modest risk of splenectomy<sup>188</sup> is preferable to the effects of long-term steroid therapy. Irradiation to the spleen has also been of benefit in patients with CLL in whom severe hemolysis failed to respond to steroid therapy, particularly in those in whom the reaction to Coombs' test was negative.<sup>193</sup> Splenic irradiation has also been of benefit in treating hemolysis in HD patients.<sup>195</sup> Spontaneous remission of hemolysis may occur.<sup>195</sup> The role of systemic antitumor therapy in treating hemolytic episodes is somewhat controversial. It has been suggested that hemolysis may be initiated by chemotherapy in CLL patients,<sup>201</sup> but decreased hemolysis has been reported following HN2 or irradiation of nodes in patients with HD.<sup>195</sup>

Fetal hemoglobin levels are abnormally high in some patients with leukemia. The highest levels, up to 76% Hb F, occur in patients with the infantile form of CML<sup>207</sup> (see Chapter 48) and in patients with DiGuglielmo's syndrome,<sup>181,186,200</sup> but modest elevation has also been observed in ALL<sup>182,207</sup> and AML patients.<sup>181,213</sup> Abnormally high levels have not been observed in patients with CLL or typical CML.<sup>181</sup> High levels may persist during complete remission in those with ALL.<sup>207</sup> The significance of the elevated Hb F remains to be determined, but its presence has led to the postulate that some forms of leukemia may involve a fetal rather than an adult stem cell.<sup>200</sup>

Hb A<sub>2</sub> has been found increased in some ALL and CML patients<sup>182</sup> and decreased in others.<sup>183</sup> Increased or decreased levels also have been reported in patients with DiGuglielmo's syndrome.<sup>183</sup> A fast A<sub>2</sub> component<sup>182</sup> and an unstable hemoglobin, probably distinct from Hb H,<sup>220</sup> have been noted.

*Red cell antigens* may be altered in some patients with acute or chronic myelocytic leukemia. This may take the form of loss of antigenicity to any isoagglutinins,<sup>190</sup> acquisition of new red cell antigens, usually A,<sup>180,210</sup> or changes in Rh grouping.<sup>216</sup> Loss of B antigen has been reported in CLL patients.<sup>211</sup>

## Complications Due to Infiltration of Organs

The frequency with which various organs are found to be infiltrated with tumor cells at autopsy<sup>3</sup> far exceeds the frequency of symptomatic complications associated with such infiltration. Differential diagnosis of complications due to infiltration, infection, or hemorrhage often presents a problem.

As a general rule, it can be stated that organ infiltration with the cells involved in leukemia, lymphoma, myeloma, and related diseases is less likely to interfere with the normal function of the infiltrated organ than when carcinomatous cells invade an organ. Thus, marked enlargement of such organs as liver and kidneys may not be accompanied by significant functional impairment.

Therapy of specific organ infiltration consists of systemic chemotherapy, local chemotherapy for certain skin lesions (page 1688), local irradiation of the involved area or surgical excision in certain selected circumstances, most notably in patients with spinal cord compression (page 1675), or the use of combined therapeutic modalities.

Therapy of extranodal infiltration given with the intent of curing the disease is limited to patients with lymphoma in a single extranodal site as, for example, the bowel (page 1682) or bladder (page 1684). In such persons the lesion usually is excised surgically for diagnostic purposes; apparent cures have followed simple surgical excision (see Chapter

51). However, it is generally recommended that excision be followed by irradiation therapy or that radiation therapy be used instead of excision if the latter was not given at the time of biopsy. Delivery of at least 3500 rads to the area of the lesion is recommended.

Palliative therapy of specific organ infiltration must be individualized, keeping in mind factors such as the extent of disease, its known responsiveness to various types of therapy, and whether or not significant symptoms or signs are the direct result of such invasion. In most instances, widespread disease is present and systemic chemotherapy is the treatment of choice. All of the tumors considered here usually are radiosensitive (Chapter 55); when reduction of a specific infiltration is urgent, local irradiation can be given in addition to chemotherapy. In some circumstances, such as in patients with CLL in whom chemotherapy may do more harm than good, or when isolated infiltrates occur in patients with acute leukemia who are otherwise in complete remission, the infiltrate may be treated with radiation therapy alone. A dose of 1000 to 2000 rads, delivered to the local lesion, usually is sufficient to accomplish palliation. Specific recommendations for therapy of specific lesions will be discussed when appropriate.

### Neurologic Involvement

The central nervous system, spinal cord, and cranial and peripheral nerves may be involved by infiltrating or compressing tumors, and symptoms may result.

#### Meningeal Infiltration<sup>273,282,283a,326,357</sup>

Patients with ALL often suffer from *diffuse* infiltration of the leptomeninges, producing what may be termed the *meningeal syndrome*. The frequency of this syndrome in different series of patients with ALL has ranged from 26<sup>282</sup> to 80%.<sup>283a</sup> The highest frequency is in recently reported series,<sup>283a</sup> and this apparent increase probably represents more frequent recognition of this complication as well as a true increase in incidence because of the lengthening life span of patients with ALL.

Meningeal infiltration may be present at diagnosis, and can develop at any time during the course of the disease. In one series<sup>253</sup> there was an accrual rate of the meningeal syndrome of 3.8% per month during the first year after diagnosis, decreasing to 2% per month during the second and third years. This syndrome has been observed in AML, but with less than half the frequency of ALL.<sup>253,282,357</sup> Its lesser frequency in AML may merely reflect the fact that remissions are less frequent and usually of shorter duration than in ALL. It is occasionally observed in patients with CLL, HD, NHL, or MM. In the last three, *patchy* tumor formation with local rather than diffuse CNS infiltration is more common than diffuse involvement.

The cerebral leptomeninges are infiltrated with lymphoblasts in a diffuse fashion and the infiltrate may extend to involve spinal meninges and the sheaths of cranial nerves. Perivascular infiltration of meningeal vessels usually is present and, although some perivascular infiltration of intracerebral vessels may also be found, frank intracerebral tumor formation is not commonly associated.

The signs and symptoms characterizing the syndrome are summarized in Table 54-3. They are primarily those of increased intracranial pressure. Headache, lethargy, nausea, and vomiting are the cardinal manifestations. Unless the patient is examined early in the evolution of the syndrome, papilledema, stiff neck, and positive Kernig and Brudzinski signs usually will be found. In young children, spreading of sutures may be observed (Fig. 54-7). Grand mal seizures may occur. However, if a high index of suspicion is maintained, a diagnosis of the meningeal syndrome often can be made when headache is the only symptom and when no abnormal signs are present. Examination of the CSF at the time of diagnosis revealed evidence of meningeal leukemia in four of 47 children with ALL in whom no symptoms or signs suggesting the syndrome were present.<sup>318</sup>

*Cranial nerve palsy* accompanies approximately 20% of meningeal syndromes. The seventh nerve is most often affected, closely followed by the sixth and third, but any nerve

Table 54-3. Signs and Symptoms of CNS Involvement Occurring in 59 Patients\*

Secondary to Increased CSF Pressure (56 Pts)		Psychic Disturbances (12 Pts)

may be involved. Localized cranial nerve involvement may occur in the absence of the meningeal syndrome (page 1675).

Fig 54-7 Widening of cranial sutures as a consequence of meningeal leukemia (From Shaw et al.<sup>357</sup> courtesy of the authors and Neurology)

Hyperphagia and obesity occasionally develop concurrently with the meningeal syndrome and are thought to reflect leukemic infiltration of the medioventral hypothalamic nuclei.<sup>221</sup>

The diagnosis is made by examination of spinal fluid. Lymphoblasts or myeloblasts in spinal fluid may be difficult to identify in routine preparations. Special means of obtaining good morphologic preparations, such as making a thin cellular preparation on plastic filters,<sup>3,36</sup> resuspending concentrated cells from spinal fluid in serum and making thin smears,<sup>361</sup> or utilizing a specially designed centrifuge for preparing smears (cyto-centrifuge),<sup>283a</sup> allow for more definitive morphologic identification than do routine methods. No increase in the number of other types of cells should be found in the spinal fluid. Rarely, no increase in the number of cells is observed.<sup>273,357</sup> The opening pressure

usually is elevated although it may not be increased early in the course of the syndrome. The protein content usually is increased and the sugar content is decreased in inverse relation to the degree of spinal fluid pleocytosis. Some investigators accept 10 mononuclear or blastic cells/ml in the absence of an identifiable organism to be sufficient evidence for diagnosis.<sup>365</sup> Still others<sup>283a</sup> consider any identifiable leukemic cells in spinal fluid to be sufficient.

The hazard of lumbar puncture with increased spinal fluid pressure does not appear to be as great in the meningeal syndrome as it is, for example, in various forms of brain tumor. Among at least 500 lumbar punctures in patients with the meningeal syndrome personally observed, herniation of the uncus occurred only once. There is a slight, but definite, hazard in doing lumbar puncture in thrombocytopenic patients. One of our patients suffered hemorrhage into the spinal canal sufficient to cause paralysis of the cauda equina. However, the need to make an accurate, prompt diagnosis of the cause of cerebral symptoms and signs in patients with leukemia outweighs the slight risk of lumbar puncture.

The differential diagnosis includes subarachnoid hemorrhage, intracerebral infiltration, and bacterial, fungal, and viral meningitis or encephalitis. The first two usually are accompanied by rapid onset of severe, localized neurologic signs, which are rare in the meningeal syndrome. Culture of spinal fluid and the presence of neutrophils and microorganisms on microscopic examination usually allow prompt recognition of bacterial meningitis as distinguished from the meningeal syndrome, and culture and India-ink preparations serve to identify fungal infection. Viral encephalitis is the most difficult differential diagnosis and it is here that good preparations for cellular identification<sup>297</sup> become critical. Lymphoblasts or myeloblasts indicate the meningeal syndrome; they are not likely to be present with any type of infection. Occasionally the meningeal syndrome and infectious meningitis coexist and then a mixed cellular picture is expected.

Meningeal infiltration often occurs in patients with ALL or AML who are otherwise in complete remission, as may other extramedullary infiltrates.<sup>355</sup> If this complication is going to develop, it usually appears during the first two years of disease (median time of onset one year).<sup>253,283a</sup> The development of the meningeal syndrome during complete remission is disconcerting; it is not known whether it develops from residual leukemic cells that were in the meninges when remission developed, from ingress of leukemic cells during "remission," or from leukemic cells newly formed in the meninges. Since none of the antitumor drugs used in remission maintenance crosses the blood-brain barrier in a concentration sufficient to kill leukemic cells, this has been suggested as the primary factor in the development of the syndrome during remission. However, the demonstration during remission of infiltrates in other areas such as the testis, ovaries, and kidneys,<sup>355</sup> which are not protected from drug exposure, throws some doubt on this hypothesis.

Although the development of the meningeal syndrome may be the first evidence of general relapse from remission, in and of itself it is not necessarily a bad prognostic sign if proper treatment is given.

### Treatment

Treatment of patients with the meningeal syndrome can be carried out with systemic drugs, steroids if the leukemia is still steroid responsive,<sup>357</sup> pyrimethamine<sup>262</sup> or BCNU,<sup>285</sup> by intrathecal installation of aminopterin,<sup>348</sup> methotrexate,<sup>465</sup> or cytosine arabinoside,<sup>376</sup> or by x-irradiation of the entire meninges. Entirely satisfactory management can be accomplished with intrathecal methotrexate (MTX) and in certain selected circumstances by whole brain irradiation. Aminopterin may have had a slightly superior ratio of therapeutic to toxic effect than MTX,<sup>348</sup> but the former drug is no longer available. Intrathecal MTX is effective even when systemic resistance to the drug has developed.<sup>365</sup> The concentration of the drug

that is achieved in spinal fluid is such that the increased dihydrofolate reductase of the MTX-resistant cell (see Chapter 55) fails to protect the cell against the drug. Considering the effectiveness of MTX, the wealth of experience with this form of therapy, and the rarity of serious toxicity accompanying its use (see below) there seems little reason to use other available forms of intrathecal therapy.

*Methotrexate*, 0.5 mg/kg, not to exceed a total dose of 20 mg, in a solution of sterile saline, is injected through the lumbar puncture needle (LP) after withdrawal of a similar or greater volume of CSF. For adequate distribution of the drug to occur, the volume of injected material is important and should exceed 10% of the CSF volume; thus, 10 to 20 ml of solution should be injected.<sup>347</sup> If the patient is kept in bed with the foot of the bed slightly elevated for an hour or two, the rate of diffusion into the cerebral space may be enhanced.<sup>347</sup> Some abatement of symptoms may be apparent immediately, presumably as the result of reduction of CSF volume and pressure.<sup>357</sup> Dexamethasone may produce prompt symptomatic relief, even in patients whose disease is no longer steroid responsive, presumably by reversing cerebral edema since neither reduced pressure nor fewer cells necessarily follow its use.<sup>321</sup> It is our practice to instill MTX with the initial diagnostic LP in any patient suspected of having the meningeal syndrome. If the diagnosis is incorrect, little harm has been done and, if correct, one additional LP for initial MTX instillation has been avoided. Lumbar puncture with MTX instillation is done twice each week until the pressure has been normalized and all leukemic cells have disappeared from the fluid. The protein concentration may remain elevated for some time after the cells have disappeared. Diffusion of MTX from the CSF is slow; treatment twice a week usually assures an effective CSF level at all times.<sup>345</sup>

Reports of serious complications relating to intrathecal instillation of MTX are few and consist of cases of *arachnoiditis*<sup>305,365</sup> and possible cases of fatal cerebral demyelination<sup>365</sup> and encephalopathy.<sup>291</sup> However, im-

mediate, transient symptoms of headache, fever, and/or vomiting were noted in 38% of patients receiving the drug for prophylactic therapy (see below); these symptoms became more severe after repeated injections had been given.<sup>366</sup> Since the slow diffusion of MTX from CSF to circulation leads to significant effects on bone marrow, the use of other drugs should be discontinued or at least their dosage should be reduced during therapy unless *citrovorum* factor is given to counteract systemic toxicity.<sup>365</sup>

Delivery of at least 1000 rads to the cerebral and spinal meninges also is quite effective.<sup>365</sup> Lower doses of *irradiation*, or omission of spinal irradiation when the skull is irradiated, either fail to correct pleocytosis or do so only transiently.<sup>365</sup> However, because of the bone marrow depression and transient alopecia associated with x-ray therapy, such therapy is usually employed only for prophylactic purposes (see below) or in a few patients who respond poorly to MTX. With any evidence of intracerebral lesions, response to intrathecal therapy is not expected to be particularly beneficial and irradiation or irradiation together with methotrexate should be employed.<sup>273,365</sup>

Prophylactic therapy of the meningeal syndrome has been shown to be feasible, at least in some patients with ALL. This topic has been reviewed in depth.<sup>283a</sup> The frequency with which the meningeal syndrome develops during initially induced remissions in children with ALL can be reduced as much as 13-fold (62% to 5%) by prophylactic therapy. Craniospinal irradiation or cranial irradiation plus repeated intrathecal MTX appear to be equally effective and are the treatments of choice. After the patient has been brought into remission by chemotherapy, CNS prophylaxis is begun. With craniospinal irradiation, 2400 rads are delivered in 24 days. In children age one to two years, the dose is reduced to 2000 rads and in those less than one year of age to 1500 rads. With cranial irradiation plus MTX, 2400 rads (or less, according to age, as described above) are given in 18 days and MTX, 12 mg/m<sup>2</sup>, is given intrathecally every three days for a

total of five injections. Lower doses of irradiation, 500 rads or 1200 rads, have little or no prophylactic effect. Intrathecal MTX without irradiation, either as a short, intensive initial course or given at spaced intervals throughout remission, has had some prophylactic effect but probably is inferior to the above-described forms of therapy. BCNU, a drug that crosses the blood-brain barrier (Chapter 55), had no apparent effect in preventing meningeal leukemia when given during remission.<sup>366</sup> Intensive systemic chemotherapy during remission may in and of itself reduce the frequency of meningeal leukemia.<sup>283a</sup>

Prophylactic regimens may have toxic effects.<sup>283a</sup> Bone marrow depression is observed, seemingly more severe with cranio-spinal irradiation than with cranial irradiation plus MTX. Approximately 10% of patients given either regimen have developed a syndrome, some five to seven weeks following radiotherapy, which is self-limited but of unknown cause and consists of fever, somnolence, dizziness, and CSF pleocytosis. Irradiation was followed by gliosis and neural degeneration in one patient, with spastic quadriplegia and mental deterioration. One patient has developed NHL of the basal ganglia and another developed CML, but whether such complications are the result of CNS therapy or of intensive chemotherapy has not been determined.

Prophylactic CNS therapy is not employed by all investigators. Since a number of patients do not develop the syndrome, they believe that such treatment is unnecessary and causes alopecia and the morbidity associated with repeated lumbar puncture and MTX installations.<sup>366</sup> However, once the syndrome has developed, and particularly if there are recurrent episodes, prophylactic therapy should be given and in such patients we have employed irradiation as well as MTX.

Recurrence of the meningeal syndrome is expected after the first episode. On the average, symptoms are again manifest within three months of adequate treatment of the initial episode.<sup>263</sup> However, recurrence may be delayed and in a few patients the syndrome

may not develop again even though they live for three or more years. A "prophylactic" regimen may not be as effective after an episode of meningeal leukemia has developed and has been treated as when it is given at the onset of remission.<sup>283a</sup>

### Localized Involvement of the Brain

Intracerebral leukemia develops in association with a rapidly rising leukocyte count in as many as 20% of patients with AML and with lower frequency in patients with ALL or in the blastic crisis of CML.<sup>150,261,326</sup> The number of blasts in the blood usually increases exponentially when these lesions develop. Autopsy examination suggests the following sequence of events: leukostasis in small vessels due to a growing mass of leukemic cells; disruption of the vessel due to the expanding mass; massive hemorrhage surrounding the growing lesion as other vessels are disrupted by the mass. The intracerebral leukemic masses are usually spherical and may be as large as golf balls. The surrounding hemorrhage may destroy large areas of the brain and multiple masses usually are found (Fig. 54-8).

Intracerebral hemorrhage, usually associated with sudden death, may be the first sign of cerebral invasion, but more often premonitory signs of headache or the sudden development of localizing neurologic signs and symptoms are present. A rapidly rising leukocyte count should be considered an indication that intracerebral leukemia probably is developing.

Therapy must be directed toward reducing the leukocyte count as quickly as possible by vigorous chemotherapy. Once symptoms or signs of intracerebral leukemia have developed, therapy is rarely of any benefit and, indeed, the complication may continue to evolve even as leukocyte counts are reduced by therapy.

*Local tumors due to NHL*, particularly Burkitt's lymphoma<sup>366</sup> and histiocytic lymphoma, may develop intracerebrally, in the dura or meninges, or in bones of the skull

Fig 54-8 A Multiple intracerebral hemorrhagic lesions in a patient with a leukocyte count greater than  $300 \times 10^9/l$  at the time of death. B, Higher magnification of the lesion in 'a' to show distinctive appearance of confluent nodules of leukemic cells surrounded by hemorrhage. C, Microscopic appearance of this type of intracerebral lesion; hematoxylin and eosin  $\times 13$  (Illustration reduced to about 42% of original size) (From Moore et al<sup>328</sup> courtesy of the authors and Archives of Internal Medicine)

with local extension compressing the cerebrum.<sup>8,250</sup> This complication is quite rare in HD<sup>1,5,250</sup> or MM.<sup>313</sup> The tumor, like any other brain tumor, produces signs and symptoms depending upon its location. Complications, such as diabetes insipidus, have resulted from small tumors infiltrating the posterior pituitary gland.<sup>303</sup> The diagnosis may be difficult to establish with certainty unless surgical exploration with biopsy is undertaken. This is usually unwarranted as most such patients have widespread disease. Examination of CSF usually discloses a high protein content, but other findings are quite variable and identifiable tumor cells are found only rarely. The lesions may be located by brain scans or by cerebral angiography. In the usual case, if no other explanation for the CNS finding is uncovered, if the picture is not compatible with multifocal leukoencephalopathy (see below), and if there is nothing to suggest brain abscess, it is assumed that a hematologic tumor involving the brain is present.

Radiation to the demonstrated mass or to the whole brain if more than one mass is present or when a mass has not been located accurately is the treatment of choice. Since cure is not to be expected, 2000 rads usually are sufficient and rarely produce any complications other than hair loss. Steroids, procarbazine, and BCNU cross the blood-brain barrier and may have a favorable effect on tumors that are sensitive to these drugs

(Chapter 55). We have observed clearing of CNS signs and symptoms in a patient with HD treated with combination chemotherapy that included prednisone and procarbazine<sup>161</sup> (Chapter 50).

*Multifocal leukoencephalopathy* is a rare syndrome affecting some patients with ALL,<sup>230</sup> HD, NHL, CML, or CLL as well as those with chronic non-neoplastic diseases such as sarcoidosis or tuberculosis.<sup>345,377</sup> Evidence for a viral cause has been presented.<sup>377</sup> The complication usually develops in severely ill patients with widespread disease, but we have observed it in a patient with well-controlled CML.

Signs and symptoms are quite variable. Widespread but erratically distributed demyelination of the CNS is found at autopsy. Vision, motor function, and speech are most often affected and signs are usually bilateral. A steady progression of disease, commonly accompanied by dementia, with death occurring within one to six months of onset of symptoms is anticipated although survival for a year has been reported, as has apparent cure following therapy with cytarabine.<sup>229,345</sup> Examination of the CSF usually reveals no abnormality or only slight increase in protein, pressure, or number of lymphocytes. The EEG, while abnormal, is nonspecific, usually showing diffuse slowing in all leads. Brain scan, arteriography, or air studies may reveal cerebral atrophy, but do not yield a specific diagnosis. Features suggesting CNS tumors

rather than multifocal leukoencephalopathy are headache, seizures, single localized neurologic signs, and significant degrees of CSF abnormality.

*Spinal cord compression* is produced by tumor in the cord, the spinal dura, or meninges; or by vertebral tumor extending into the spinal canal and compressing the cord; or as a result of vertebral collapse and spinal cord compression. It is common in MM, affecting as many as 20% of patients<sup>3</sup>; it is present in 3 to 8% of HD patients.<sup>332,359</sup> It is less common in patients with NHL,<sup>359</sup> and is rare in those with leukemia although it can occur in association with any form of leukemia.<sup>389</sup>

There may be premonitory symptoms, such as paresthesias for days or weeks, but in some patients the interval between the first symptoms and complete paraplegia is measured in hours. Since recovery from paraplegia is unusual, any symptom suggesting cord involvement should lead to immediate complete evaluation. Therapy depends, in part, upon the severity of the signs and symptoms.<sup>332,359</sup> If severe paraparesis is evident, the myelogram should be obtained in the operating room and the area shown to be affected should be explored immediately. Postoperative irradiation therapy is advisable even when it is believed that most of the tumor has been removed surgically. If symptoms and signs have not progressed beyond the point of mild paresis, a trial of irradiation therapy may be given, but immediate laminectomy should be planned if any progression of signs occurs. Systemic chemotherapy should be given concurrently, especially when rapid response to therapy can be anticipated, as in HD.<sup>359</sup> Regression of mild paraparesis has followed chemotherapy alone in Burkitt's lymphoma.<sup>386</sup>

The urgency of therapy in this complication cannot be stressed too strongly. When treatment is delayed until the lesion has produced paraplegia, the latter almost always proves permanent, despite surgical and irradiation therapy.

*Cranial nerves* may be involved because of local infiltration after leaving the brain or as part of the meningeal syndrome (page 1669),

or tumor may involve their cerebral origins. The seventh nerve is most often affected peripherally, in which case a "peripheral" rather than a "central" facial palsy will ensue. Unilateral papilledema, proptosis, deafness, or vestibulatory disturbances are other findings that may be due to peripheral cranial nerve infiltration, and bilateral optic nerve infiltration, persisting after other manifestations of the meningeal syndrome had disappeared, has been observed.<sup>251a</sup> X-irradiation to the track of the nerve as it leaves the specific foramen of the skull is the treatment of choice.

*Peripheral nerves* are affected occasionally, usually due to compressing tumor masses. With HD or NHL, axillary or supraclavicular masses may cause pressure damage to nerves of the cervical plexus, and retroperitoneal nodes may compress lumbar or sacral nerve roots. Infiltration of dorsal root ganglia or of peripheral nerves themselves may occur with leukemia, lymphoma, or myeloma.<sup>247</sup> Peripheral neuropathy, with no apparent cause, has been reported.<sup>233,248</sup>

## Ocular Disease

Abnormalities of the orbit and of the globe or the nerves of the eye are rather frequent, although, in patients with HD, involvement of the globe is quite rare.<sup>223</sup> Fundic hemorrhage is common and usually is due to anemia,<sup>1</sup> although thrombocytopenia (page 1662) and leukemic infiltration in the retina<sup>223</sup> may contribute to this complication. Tumors of the orbit, displacing the globe and producing proptosis, may occur occasionally with any type of leukemia or lymphoma, but are most common in children with AML (*chloroma*) (Chapter 47). Cranial nerve involvement affecting the eye has been discussed above.

Although various portions of the globe may be infiltrated, the avascular cornea and lens are usually, but not invariably, spared this complication<sup>223</sup> (Fig. 54-9). Small infiltrates in the conjunctiva or the sclera, sometimes visible grossly, but usually asymptomatic, may be observed in patients with any

Fig 54-9 Lymphocytic tumor of cornea in patient with chronic lymphocytic leukemia

form of leukemia or lymphoma as well as in those with myeloma.<sup>223</sup> Choroidal and iris infiltration, most common in AL patients, are likewise usually asymptomatic but have resulted in such complications as glaucoma in ALL<sup>258</sup> and CLL patients<sup>269</sup>, lesions with the appearance of an hypopyon in AML and NHL patients<sup>293</sup>, and macular detachment in those with ALL.<sup>387</sup> X-irradiation of the orbit was beneficial in all of these patients.

Nodular or diffuse infiltration of the retina has been associated with various forms of leukemia or lymphoma,<sup>223,301</sup> and the vitreous body has been infiltrated in MM and AL subjects.<sup>223</sup> These infiltrates may be associated with areas of retinal necrosis, retinal detachment, and visual symptoms.<sup>223</sup> They may be seen with an ophthalmoscope. Increased tortuosity of the vessels<sup>320</sup> and microaneurysms<sup>251</sup> have been observed in the fundus of patients with CLL and of those with CML.<sup>251</sup>

#### Ears, Nose, Throat, Larynx, and Oral Cavity

The ears may be affected by hemorrhage,<sup>332</sup> infection (page 1656), or central nervous system or cranial nerve infiltration (pages 1669-1675) with hearing deficit, tinnitus,

pain, or vertigo resulting.<sup>353</sup> Symptoms due to infiltration of the structures of the inner ear are uncommon.<sup>306,351</sup>

The nasopharynx, pharynx, and larynx, when involved by infiltrative disease, usually are affected by involvement of Waldeyer's ring (adenoids, tonsils, and lymphoid tissues on the posterior pharyngeal wall and at the base of the tongue) by lymphoid neoplasms (see Chapters 47, 48, 49, 50, 51, and 52 and Fig. 51-3). Rhinophyma has been reported as being due to CLL.<sup>2</sup> Blockage of nasal passages due to AML infiltrates has occurred<sup>272</sup> and NHL of the nasal septum has produced a picture similar to that of idiopathic midline granuloma.<sup>286</sup> Laryngeal infiltration, severe enough to require tracheostomy, has occurred in patients with AML.<sup>289</sup>

The mouth and gums are rarely infiltrated except in persons with the monocytic variants of AML (Chapter 47).

Infiltration of the salivary glands producing reduced saliva and symptoms and signs reminiscent of Mikulicz's<sup>327</sup> or Sjögren's<sup>367</sup> syndromes has been observed in association with the acute leukemias<sup>1</sup> (Fig. 54-10).

#### The Lungs

*Infiltration of the pulmonary parenchyma* severe enough to be demonstrable in chest x rays is common in HD, is observed with some frequency in NHL, ALL, and AML, and during the blastic phase of CML, but is quite unusual in CLL or MM.<sup>2,6,9,296,333</sup> In as many as 10% of patients with HD there is pulmonary involvement at the time of diagnosis and probably at least half of those who are not cured eventually have this complication (see Chapter 50). In HD and NHL patients, pulmonary disease usually is the result of direct extension from disease in mediastinal or hilar lymph nodes, but lesions more distal and seemingly the result of blood-borne metastases also occur. In leukemia, association of the pulmonary infiltrate with disease in the hilum usually is not apparent.

Hodgkin's disease and NHL apparently limited to the lung and without associated hilar or mediastinal disease may occur.<sup>5,8</sup> It

Fig 54-10 Mikulicz's syndrome in a patient with chronic lymphocytic leukemia. Note the symmetrical swelling of the lacrimal and salivary glands. There was no leukocytosis ( $WBC\ 7.7 \times 10^9/l$ ), and only moderate lymphocytosis (lymphocytes 86%). The patient died of lobar pneumonia; the diagnosis was confirmed at autopsy. (From Jacobsen and Schaffer,<sup>285b</sup> courtesy of the authors and American Journal of Diseases of Children.)

has been suggested that certain lymphocytic tumors are not truly lymphosarcoma in that the eventual development of disseminated LSA after their surgical removal has been quite unusual as compared to those in which the pathologic appearance was that of RSCa.<sup>351</sup>

There is nothing diagnostic about the roentgenographic appearance of pulmonary infiltrates. For example, there may be single or multiple discrete rounded tumors of any size, massive invasion of a lobe, miliary lesions throughout the lung, or simply increased density of "pulmonary markings" in a part of or in all the lung. Cavitation of infiltrates has been observed in patients with HD<sup>363</sup> and AL.<sup>385</sup> Pulmonary infarction due to leukemic cells obstructing vessels may occur in patients with AL.<sup>285</sup> The lesions may be asymptomatic or may be associated with cough, chest pain, increased sputum production, and/or hemoptysis. Respiratory obstruction and atelectasis due to endobronchial HD have been noted.<sup>363</sup> Diffuse infiltrates may compromise lung function, pro-

ducing decreased lung volume, reduced carbon-monoxide diffusing capacity, and hypoxemia. Alveolocapillary block has resulted from infiltration in AL and CLL patients and respiratory distress was the presenting complaint of a patient with ALL in whom the alveolar walls were infiltrated.<sup>263</sup>

Differential diagnosis between tumor infiltration, infection (page 1656), and hemorrhage due to thrombocytopenia (page 1662) often is quite difficult. Pulmonary embolus with infarction can occur, even in thrombocytopenic patients.<sup>379</sup> Pulmonary alveolar proteinosis has complicated CML,<sup>249</sup> and hyaline membrane formation has been associated with HD.<sup>238</sup> Microscopic and cultural examination of the sputum for infecting organisms is important in the differential diagnosis. When uncertainty exists as to whether the lesion is due to tumor or infection it is usually wise to institute an appropriate therapeutic trial for infection. For instance, if there is any reason to suspect pulmonary tuberculosis, it is wise to institute INH therapy even if tuberculosis has not been proved. In certain

circumstances, biopsy proof of the diagnosis should be sought, as, for example, when endobronchial lesions accessible to bronchoscopy are present.<sup>363</sup> If the lesion is in the periphery of the lung, a needle biopsy may be attempted if blood coagulation is normal. Thoracotomy with open lung biopsy can be justified in certain circumstances. Determining the exact nature of pulmonary infiltration at the time of diagnosis of HD is quite important in staging patients and deciding upon the proper type of therapy (see Chapter 50). A growing "coin" lesion excised from one of our asymptomatic patients with CLL proved to be a histioplasmoma.

Therapy of patients with pulmonary infiltration depends upon the type and stage of disease. If HD is otherwise localized and if the pulmonary infiltrates are small and contiguous with hilar or mediastinal disease, "curative" radiotherapy should be directed to the lesion, especially in patients in whom this is found at the time of diagnosis (Chapter 50). However, since the lung is quite sensitive to damage by radiotherapy (Chapter 55), chemotherapy is the treatment of choice in most cases of pulmonary infiltration in leukemia and lymphoma.

Mediastinal structures, commonly lymph nodes, but also the *thymus*, may be infiltrated in patients with ALL,<sup>1,267</sup> CLL,<sup>2</sup> HD,<sup>5</sup> or NHL.<sup>6</sup> An extreme degree of mediastinal enlargement may occur without evident symptoms, but the trachea or superior vena cava may become obstructed.

The *pleura* may be infiltrated with small plaques, or diffusely, in patients with HD,<sup>363</sup> AL,<sup>333</sup> or NHL<sup>6</sup> and we have observed massive, diffuse infiltration of the pleura in one patient with MM. Pain with respiration may be present and pleural effusion usually occurs.

*Serous effusions* of the pleural space, but also of the peritoneal and even pericardial cavities, are common in HD and NHL, complicating the clinical course of 20 to 30% of patients who are not cured.<sup>317</sup> Pleural effusions were found in 60% of autopsied patients with HD in one series and ascitic fluid was present in 44%.<sup>3</sup> Careful cytologic examina-

tion of the effusion revealed diagnostic lymphoma cells in 56% and cells suggestive of lymphoma in another 14%.<sup>317</sup> Thus, it seems likely that infiltration of the serosal surface of either visceral or parietal pleura is the most common cause of effusion. However, autopsy evidence of infiltration was not present in the serosal surface of some patients with effusion.<sup>5,6</sup> Lymphatic obstruction due to enlarged nodes and hypoalbuminemia may contribute to effusion in such patients. Serous effusion also occurs in patients with AL,<sup>1,333</sup> CLL,<sup>2</sup> and CML,<sup>243</sup> but is unusual in those with MM.

When pleural or peritoneal fluid is detected, the fluid should be aspirated for diagnostic purposes unless thrombocytopenia is extremely severe. Infectious exudates or hemorrhage will be present occasionally, even when unsuspected from ancillary signs and symptoms. Chylothorax or chylous ascites may be present, presumably due to obstruction of major lymphatic channels, such as the thoracic duct,<sup>371</sup> by lymphoma<sup>317</sup> or CLL.<sup>300</sup>

Treatment of serous effusions depends, in part, upon their cause. Instillation of anti-tumor drugs into the cavity can be expected to influence serosal or free-growing tumor cells, but will have no effect on lymphatic or venous blockade by tumor and little effect on large, local tumor masses. In general, a trial of systemic chemotherapy is warranted. Intracavitary instillation of drugs should be used for troublesome, recurrent effusions primarily. Instillation of nitrogen mustard (HN2) into the pleural cavity<sup>314,378</sup> remains our treatment of choice because of its high rate of effectiveness after a single dose, relative inexpensiveness, and relative freedom from toxic side effects. Nitrogen mustard is instilled in a dose of 0.4 mg/kg, or less if the marrow is depressed. Some diffusion of HN2 from the cavity is anticipated so that systemic effects may be induced. As much fluid as possible should be removed before instilling HN2 to ensure a high concentration of the drug at the site of tumor. The patient should change position repeatedly and frequently, immediately after instillation of HN2, to aid distribution of the drug throughout the cav-

ity. Pain is rare after intrapleural injection, but is more common after intraperitoneal injection.<sup>314,378</sup> The immediate result may be a rapid increase in fluid, perhaps due to induced inflammation. Indeed, inflammation of the serosa with resultant adhesion between visceral and parietal pleura may be the mode of action of the drug in some circumstances. The possibility of inducing bowel adhesion has made us reluctant to inject HN2 into the peritoneal cavity, but this has been done.<sup>314,378</sup> One dose of HN2 is often sufficient, but the dose may be repeated at intervals of three to four weeks if needed. Intrapleural quinacrine induces a fibrothorax and thereby leads to control of pleural effusion.<sup>248,278</sup> However, the pain and fever resulting from its injection, the need for repeated instillation at frequent intervals, the often delayed response to therapy, and the uninterpretability of future x rays due to the massive pleural thickening caused by quinacrine lead us to prefer HN2. Other agents that have proved helpful in intracavitary treatment of neoplastic effusions include thio-tepa,<sup>372</sup> 5-fluorouracil,<sup>364</sup> and radioactive gold and phosphorus.<sup>239</sup>

### Cardiovascular System

While cardiac infiltration, particularly of the pericardium, can be detected at autopsy in a small but significant number of patients who have died with leukemia, lymphoma, or myeloma,<sup>3,7,9</sup> symptoms and signs are rarely attributable to leukemic infiltration during life. Most instances of arrhythmia, congestive failure, or pericarditis are explainable on the basis of anemia, electrolyte disturbances, infection, hemorrhage,<sup>257</sup> or other secondary factors. However, in certain patients, such factors have not been present and the symptoms and signs have then been attributed to cardiac infiltration because they disappeared following x-ray therapy to the heart, or after chemotherapy. Signs and symptoms of *pericarditis* with pericardial effusion and presumably due to leukemic infiltration of the pericardium have been observed in HD, ALL,<sup>1</sup> AML,

CML,<sup>232</sup> and NHL patients.<sup>6</sup> Pericardial infiltration has been observed during the course of AML when the patient was in bone marrow remission.<sup>228</sup> This is usually a presumptive diagnosis; however, leukemic cells have been demonstrated in pericardial effusions.<sup>328</sup>

Congestive heart failure has been attributed to myocardial infiltration in ALL<sup>279</sup> and CLL.<sup>227</sup> Complete heart block, apparently due to infiltration of the septum, has been reported in association with AML.<sup>250</sup>

*Nonbacterial thrombotic endocarditis* appears to be more frequent in patients with HD, as well as in those with various forms of carcinoma, than in patients dying of non-malignant causes.<sup>349</sup> The nonbacterial endocarditis which is found in patients with "acute eosinophilic leukemia" has been discussed (Chapter 47).

*Vascular obstruction* due to rapidly growing intravascular masses of leukocytes during periods of rapidly increasing leukocyte counts in AL patients is associated with intracerebral leukemia (page 1673). Patients may suffer fatal hepatic and pulmonary destruction by a presumably similar mechanism; any organ can be affected by this process.<sup>316</sup> Infiltration of venous valves has been reported as a cause of venous insufficiency of the legs.<sup>299</sup> However, venous obstruction of clinical significance is more often due to extrinsic masses pressing on large veins than to intrinsic disease of the veins.

The superior vena cava syndrome occasionally is associated with mediastinal lymph node infiltration or with thymic infiltration (page 1678). The inferior vena cava syndrome<sup>229</sup> may be produced by enlarged retroperitoneal nodes in patients with lymphoma. Lymphatic obstruction, hepatic disease, and hypoalbuminemia may contribute to the massive, distal edema associated with obstruction of the vena cava.

Therapy of obstruction of the vena cava should be prompt and vigorous. The site of obstruction can be located accurately by means of venacavography; irradiation directed toward that specific site and concurrent chemotherapy are indicated. Therapy with adrenal corticosteroids is often of benefit,

perhaps by reducing inflammation as well as by shrinking the tumor.

### Breast

The breast occasionally is infiltrated in ALL<sup>1</sup> and AML<sup>354</sup> patients; the infiltration may be diffuse, producing symmetrical breast hypertrophy and even lactation, or it may be nodular.<sup>291a,330</sup> In patients with NHL<sup>8</sup> or HD,<sup>15</sup> nodular breast masses may occur. Localized blastic tumors of the breast have appeared as the first evidence of developing blastic crisis in patients with CML (Chapter 48).

### Liver

Hepatic infiltration and enlargement are commonly associated with AL, CLL, HD, NHL, and with the blastic crisis of CML, but are unusual in MM patients. Infiltration may be diffuse or nodular in nature (Fig.

54-11) in HD, NHL, and in the very rare patient with MM. Leukemic infiltration almost always is diffuse in nature. In AML and CML, leukemic cells are concentrated in perivascular areas, while ALL and CLL more often are associated with marked infiltration of the portal spaces.<sup>3,270</sup> Hepatomegaly may also be the result of hypertrophy of hepatocytes in the leukemias.<sup>259,382</sup>

Evidence of hepatic dysfunction may be absent, particularly in the leukemias, even when hepatomegaly is quite prominent. When troublesome hepatic dysfunction does occur it is usually accompanied by *jaundice*.<sup>308</sup> While jaundice may be due to a variety of complications such as viral hepatitis, bacterial infection, or toxicity from antitumor therapy (Chapter 55), it most often reflects infiltration of the liver by tumor, at least in patients with HD.

Jaundice has been reported in 13% in each of two large series of patients with HD, but its incidence may exceed 50% when analysis

Fig. 54-11 Nodular infiltration of the liver in Hodgkin's disease

is limited to patients dying with HD.<sup>6</sup> The jaundice most often is due to invasion of the liver, less commonly to extrahepatic bile duct obstruction, but it may also reflect hemolytic anemia or be due to other causes.<sup>294</sup>

Obstruction of the common bile duct can occur as the result of infiltration of the duct, compression of the duct by lymph nodes, or even gallbladder infiltration.<sup>374</sup> Obstruction of small biliary radicals may result in a clinical picture similar to that of obstruction of the common duct.<sup>311</sup> Obstruction of the common bile duct accounts for only 3 to 10% of HD patients who are jaundiced.<sup>6</sup>

Portal obstruction by infiltrates in portal spaces with development of esophageal varices has been reported in HD<sup>307,354</sup> and in CLL.<sup>338</sup> Extrahepatic portal vein obstruction has been noted in HD.<sup>308</sup> Hepatic fibrosis with portal hypertension also occurs as a complication of methotrexate therapy (Chapter 55). Portal vein thrombosis in association with thrombocytosis in CML has been reported,<sup>354</sup> but is rare.

Accurate differentiation of the various causes of jaundice is important, but, except for distinguishing jaundice due to hemolysis from jaundice due to liver disease, this is often a difficult task. Clinical features and liver function tests usually are of little help in differentiating liver disease due to tumor invasion from that due to other causes.<sup>6</sup> Alkaline phosphatase and leucine aminopeptidase are often, but not invariably, elevated with tumor invasion. Liver biopsy can be quite helpful and is indicated unless coagulation is abnormal or posthepatic biliary obstruction is suspected.

Systemic chemotherapy is the treatment of choice for hepatic infiltration with hepatic dysfunction. Irradiation, not to exceed 2000 rads, can be given to the entire liver (see Chapter 55) and, if common duct obstruction due to tumor is suspected, irradiation of the area of that structure may be advisable.

### Spleen and Lymph Nodes

The spleen and lymph nodes are less commonly involved in MM and related diseases

(Chapters 52 and 53) than in leukemia (Chapters 47, 48, and 49) or in the lymphomas (Chapters 50 and 51). In most instances it is difficult to attribute specific complications to lymph node or spleen involvement, although, as discussed (page 1663), increased sequestration and/or destruction of normal blood cells can be attributed to splenomegaly in occasional patients.<sup>244</sup>

*Splenic infarction* and, more rarely, *splenic rupture* may occur. Splenic infarction, if it involves the serosal surface of the spleen, may be accompanied by symptoms, as well as signs, suggestive of the primary process. These depend upon whether the inflamed splenic surface infringes upon and irritates the peritoneum, producing left upper quadrant pain, or the serosal surface of the diaphragm, producing pain in the left side of the chest or even in the left shoulder. In either case, auscultation of the left upper quadrant often discloses a rub which is accentuated by deep inspiration, as is pain. Splenic infarction, as judged by the signs and symptoms described above as well as by autopsy,<sup>1,2,3,5,7,8,367a</sup> occurs infrequently in AML or CML and is rare, but may occur, in ALL, CLL, and NHL. It is most unusual in MM.<sup>299</sup>

Rupture of the spleen has been reported as the first manifestation of CML,<sup>315</sup> ALL, or AML<sup>383</sup> and may be observed in patients with CLL,<sup>271</sup> but is a most unusual<sup>290</sup> complication in these disorders or in lymphoma or myeloma,<sup>284,299</sup> despite the frequency of splenic enlargement.

There is no consistent relationship between splenic infarction and splenic rupture. Therapy of the former is limited to simple observation. Symptoms usually disappear within three to five days. If signs of splenic rupture are present (generalized peritoneal irritation with severe pain in the left upper quadrant), immediate surgical exploration with splenectomy is the treatment of choice.

### Gastrointestinal Tract<sup>343</sup>

**ESOPHAGUS.** Symptomatic infiltration of the esophagus is quite rare, but dysphagia due

to infiltration in ALL<sup>226</sup> and dysphagia and obstruction in AML<sup>256</sup> have been reported, as has bronchoesophageal fistula in HD.<sup>328a</sup> Esophageal infiltration has been the site of fatal hemorrhage in ALL.<sup>343</sup>

**STOMACH** As discussed in Chapter 48, peptic ulceration is a common complication in CML as it is in polycythemia vera (Chapter 30), although symptomatic leukemic infiltration of the stomach in CML is most unusual.<sup>241</sup> The frequency of symptomatic infiltrates is difficult to establish since many of the drugs used in therapy produce gastric symptoms. Ulcerated leukemic infiltrates have been observed at autopsy in AML and ALL patients.<sup>343</sup> Massive infiltration (see Fig. 51-6) with retention of gastric contents is observed rarely in patients with acute or chronic leukemia, HD, or NHL.<sup>211,343</sup> Hyperacidity has been reported in children with ALL.<sup>369</sup>

**BOWEL.** Infiltrates of the bowel in acute and chronic leukemia, NHL, and HD are more often found in the small than in the large intestine and are more frequent in the distal ileum than in the proximal small intestine.<sup>319,343</sup> These infiltrates often appear to be portals of entry for infection by intestinal bacteria. Perforation and fistula formation may occur and large areas of gangrenous bowel may be found.<sup>343</sup> Perforation due to rapid lysis of lesions by chemotherapy has been noted in HD.<sup>6</sup> Nodular lesions or lesions that become polypoid occur in all forms of leukemia<sup>313</sup> and have been associated with intussusception and intestinal obstruction.<sup>274,297,298,362</sup> Massive, diffuse infiltration of large segments of the stomach or bowel is seen occasionally in CLL (Fig. 54-12)<sup>313</sup> and has been noted during bone marrow remission in acute leukemia.<sup>255</sup> We have observed a patient with NHL in whom virtually the entire bowel was infiltrated. Diffuse or multifocal lesions of NHL, and less commonly of HD, in the proximal small intestine may produce severe degrees of malabsorption.<sup>337,344</sup> This syndrome seems to be much more common in Arabs, Sephardic Jews,

Mexicans, and the South African Cape colored than in the general population of the United States.<sup>337,344</sup> It may be more common when NHL is limited to the bowel than as a secondary feature of NHL.<sup>337,344</sup>

Primary NHL of the bowel is discussed in Chapter 51. HD apparently originating in and limited to the bowel may occur.<sup>6</sup>

Lesions located in the sigmoid colon and rectum are frequently associated with symptoms of rectal pain and mucosanguineous diarrhea.<sup>343</sup> As noted elsewhere (page 1656), rectal infections are serious complications in ocrotropic patients.

So-called pseudo-acute abdomen has been reported in ALL and AML<sup>343</sup> as well as in HD.<sup>215</sup> Signs and symptoms suggesting intestinal obstruction with perforation and peritonitis were present, but at operation or autopsy no perforation could be demonstrated.

### Renal Complications

The renal complications seen in multiple myeloma and related diseases that are primarily associated with overproduction of light chains are discussed in Chapter 52. Symptomatic complications or significant impairment of renal function is more often due to pyelonephritis (page 1656), hemorrhage (page 1662), hyperuricemia (page 1689), hypercalcemia (page 1692), drug toxicity (Chapter 55), or ureteral obstruction by tumor masses (page 1684) than to renal infiltration.<sup>345</sup> Nevertheless, infiltration of kidneys producing renal failure may occur in leukemia and lymphoma.<sup>5,8</sup> In a series of 178 patients with AML and ALL, four developed otherwise unexplained azotemia in association with markedly enlarged, infiltrated kidneys.<sup>260</sup> However, normal renal function has been noted in other patients with AL in whom marked renal enlargement and infiltration were present.<sup>260</sup> Functional impairment also has been reported in a few patients with CLL, HD, or NHL when there was diffuse or nodular infiltration.<sup>346,356</sup> The nephrotic syndrome,<sup>356</sup> as well as azotemia,<sup>346,356</sup> may be associated with such infiltration, but fewer than 10% of patients with HD or NHL in-

Fig 54-12 Enormously enlarged stomach with mucosa thickened and thrown into huge convolutions in a patient with chronic lymphocytic leukemia (WBC  $86 \times 10^9/l$  lymphocytes 96%) Some of the convolutions were as much as 2 cm thick and 2 cm high

volving the kidneys at autopsy exhibited azotemia<sup>346</sup> from any cause.

The diagnosis of impairment of renal function due to renal invasion by leukemia or lymphoma is one of exclusion. The urinary findings are nonspecific, consisting primarily of albuminuria, rarely of hematuria and pyuria.<sup>346,356</sup> Since most infiltrates are not associated with impairment, biopsy proof of infiltration does not indicate that impairment is due to infiltration. In the absence of hyperuricemia, hypercalcemia, positive urine culture, or recent therapy, particularly x-ray therapy to renal areas, and in the presence

of roentgenographic evidence of renal enlargement or tumors one assumes that renal invasion is the correct diagnosis. Intravenous pyelography poses some hazard to patients with multiple myeloma in that anuria and even death have been reported to follow the procedure<sup>305a</sup> (Chapter 52). While it has been suggested that this does not occur unless the patient is dehydrated<sup>305a</sup> we have observed sudden onset of anuria following an IVP in a patient with MM in whom no dehydration was induced. "Test doses" of the dye used in pyelography have no value in predicting subsequent fatal reactions.<sup>257a</sup>

Therapy of renal infiltration is best accomplished by systemic chemotherapy, but if this proves of no avail x-ray therapy may be directed to the kidney.<sup>246, 256</sup> However, dosage should probably not exceed 1000 rads as the kidney is easily damaged by irradiation (Chapter 55).

Renal hypertrophy without leukemic infiltration and also without functional impairment is fairly frequent in AL and is of unknown cause.<sup>264</sup>

The *nephrotic syndrome*, in the absence of renal infiltration and without other demonstrable cause, may develop in association with HD.<sup>246, 256a, 277, 283, 288</sup> There are at least 30 case reports dealing with such occurrences. The disappearance of the syndrome with therapy of HD suggests a causative relationship,<sup>246</sup> and a similar observation has been made in Burkitt's lymphoma.<sup>283</sup> However, how HD, in some cases localized to distant structures such as the mediastinum,<sup>277</sup> can produce a nephrotic syndrome remains to be clarified. It has been suggested that this is immune complex renal disease, representing deposition of tumor specific antigen-antibody complexes;<sup>256a, 293;</sup> such deposits have been demonstrated in glomeruli of mice with spontaneously occurring leukemia.<sup>237b</sup> The nephrotic syndrome also has been associated with CLL in the absence of renal infiltration, but in these cases there was excessive production of light chains.<sup>236</sup> Therefore, the nephrotic syndrome may have been produced by the same mechanism as is suggested in MM (Chapter 52). A patient with RCSa associated with anasarca and hypoproteinemia, but without proteinuria, which were reversible with therapy and was thought to be due to infiltration has been reported.<sup>295</sup>

### Genitourinary Tract<sup>310</sup>

The testes, penis, bladder, ureters, prostate gland, uterus, and ovaries may be infiltrated by tumor. Infiltration of these organs is most common in AL. Testicular infiltration, unilateral or bilateral, occurs in a small percentage of patients with ALL; the testis is one of the sites in which localized leukemia

develops in patients who otherwise remain in complete remission.<sup>1</sup> The testes may be involved in lymphoma. A testicular mass may be the presenting complaint of such patients, but generalized disease usually is found.<sup>276</sup> Involvement is most often unilateral, but subsequent invasion of the opposite testis is fairly common.<sup>276</sup> In one of our patients, a 10 year old boy with ALL, removal of one involved testis was followed by infiltration of the other within six months, although the patient remained in complete remission otherwise throughout this period and for two years following irradiation therapy to the second testis.

*Priapism* is observed in an occasional patient with CML or AL and persistent clitoral engorgement has also been reported in patients with CML.<sup>331</sup> Priapism is thought to be due to infiltration of the corpora cavernosa and may regress following systemic chemotherapy or local irradiation.

*Prostatic infiltration* producing obstructive symptoms has been reported in AML and CLL patients; it developed during bone marrow remission in one patient with AML.<sup>322</sup> The *bladder* may be infiltrated in any form of leukemia or lymphoma.<sup>268, 275</sup> Though rare,<sup>6, 268</sup> more than 40 cases of NHL apparently localized in the bladder have been reported.<sup>375</sup> If symptoms are produced by bladder lesions, they consist of those associated with any tumor of the bladder, such as hematuria, dysuria, and frequent urination.

Ureteral infiltration, severe enough to produce obstructive uropathy, has been noted in NHL, HD, and CLL.<sup>268</sup> Ureteral obstruction is likely to be due to encroachment upon ureters by enlarged retroperitoneal nodes.<sup>8</sup>

Invasion of uterus and ovaries may occur, but rarely produces symptoms.<sup>3, 381</sup> However, fatal ovarian hemorrhage has been reported.<sup>159</sup>

### Endocrine Glands

Infiltration of the *thyroid gland* may lead to goiter in patients with HD,<sup>8</sup> as may hemorrhage into this gland in those with AML.<sup>351</sup> Although the basal metabolic rate

is often increased in leukemia and lymphoma, thyroid dysfunction is unusual (page 1688). Lymphomatous tissue may take up radioactive iodine at a greater rate than does normal, nonthyroidal tissue, leading to low thyroid uptake without hypothyroidism.<sup>310</sup>

The adrenal gland rarely is affected significantly by infiltration in leukemia and lymphoma. Small infiltrates have been demonstrated at autopsy in a few patients,<sup>3,7</sup> but studies of adrenal hormone secretion disclose normal or slightly increased secretion, presumably as a nonspecific response to stress.<sup>339,350</sup> Hemorrhage into the adrenals has been considered a cause of death in a patient with CML.<sup>304</sup>

The endocrine function of the pancreas usually is normal. Hypoglycemia does not appear to be a complication of hematologic neoplasms although it may occur artifactually in leukemia when the blood leukocyte count is markedly elevated.<sup>397,417</sup> Glucose is utilized by leukocytes in blood samples after they have been drawn unless a larger than normal amount of sodium fluoride is added to inhibit glycolysis. Onset of diabetes has been noted coincidentally with onset of leukemia,<sup>415</sup> but most diabetic problems are associated with adrenal corticosteroid therapy (Chapter 55). Diabetes insipidus has been produced by infiltration of the posterior pituitary in AL<sup>321</sup> and CML patients.<sup>304</sup> Forty-six percent of 52 patients with AL were found to have peripituitary gland infiltration, but in none was there evidence of clinically significant dysfunction.<sup>314a</sup> Inappropriate antidiuretic hormone secretion has been reported in at least five patients with HD; this disappeared with chemotherapy of HD. The source of the hormone, whether from pituitary gland or from tumor elsewhere, has not been established.<sup>240</sup> Ovarian and testicular involvement were discussed in the preceding section.

### Musculoskeletal System

Destruction of bone with severe pain is much more commonly associated with MM (Chapter 52) than with other hematologic

neoplasms. The reason for this tumor's bone-destroying propensity has not been clarified. Bone pain with roentgenographic abnormalities of bone is common in AL, occurs with some frequency in NHL and HD, and is rare in CLL and in CML except during blastic crises.<sup>329,368</sup>

Bone pain occurs in approximately 50% of patients with AL<sup>368</sup> and is somewhat more common in ALL than AML patients of any age. In children with ALL the pain is most often in the long bones, while in adults with AML it more often is in ribs and vertebrae.<sup>368</sup> Diffuse osteoporosis, associated with enlargement of haversian and Volkmann's canals by leukemic infiltration, probably accounts for some instances of bone pain. Radiolucent metaphyseal bands are present in the long bones of almost all children with AL (Fig. 54-13). These are not due to leukemic infiltration and do not correlate with bone pain but represent arrest of bone growth during periods of active disease. The number of relapses and remissions that children have experienced is often mirrored by a like num-

Fig. 54-13. Metaphyseal lines in the tibia of a child with ALL.

Fig. 54-14 Roentgenograms of the humerus of an 11 year old girl with acute lymphoblastic leukemia. Note the irregular distortion of the architectural pattern and the multiple defects within the medullary portion of the bone: the decalcification of the cortex on the mesial aspect of the shaft and the periosteal proliferation.

ber of metaphyseal bands. Osteolytic lesions, resulting from leukemic infiltrates, or less often from bone infarcts, are common and may be associated with pain.<sup>334</sup> Cortical destruction (Fig. 54-14) with or without periosteal elevation appears to be the most common cause of pain in the extremities in ALL patients. Necrosis of bone from bone infarcts produces pain before it is demonstrable roentgenographically. Pain from bone destruction may be the primary symptom of blastic crisis in CML.<sup>342</sup>

Bone pain and bone lesions occur in perhaps 10% of patients with HD or NHL (Fig. 54-15). They may represent invasion of bone from lesions in bone marrow or direct extension to bone from disease in lymph nodes. Osteolytic areas of bone are more usual (Fig. 54-16), but an osteoblastic x-ray picture may also be observed.

Pathologic fractures are unusual, except in patients with MM (Chapter 52), but have been reported in AL, CLL, NHL, and HD.<sup>312,368</sup>

Metastatic acropachy with extreme enlargement of the terminal phalanges due to infiltration has been reported in a patient with CLL.<sup>237</sup>

*Joint pain* occurs in 10 to 20% of patients with AL, but is uncommon in those with CML, CLL, or lymphoma.<sup>368</sup> Arthritis as

Fig. 54-15 Destructive process involving the proximal end of the right radius with marked periosteal reaction over it, in a patient with lymphosarcoma (lymphoblastic lymphoma).

Fig 54-16 Lymphogranulomatous lesions in the marrow in a patient with Hodgkin's disease. A, Manubrium and half of the sternum. B, Transection through the fourth lumbar vertebral body and C, mid-dorsal vertebral body. D, Right iliac crest, and E and F the right third and second ribs. G, The only bone without a lesion, the left first metatarsal (Steiner,<sup>364</sup> courtesy of Archives of Pathology.)

well as arthralgia may be present. The arthritis tends to be symmetrical and migratory and most commonly involves the hands, feet, elbows, ankles, and knees. The cause of the arthritis is not entirely clear; the condition may be due to infiltration of the metaphyseal periosteum subjacent to the joint capsule with associated inflammation and effusion.<sup>368</sup> Synovial infiltration is quite rare.<sup>368</sup>

Muscle infiltration by leukemia or lymphoma is most unusual. Polymyositis of unknown cause has been associated with AML<sup>254</sup> and complaints of muscle ache are not uncommon in patients with AL.

## Skin

Disease, apparently primary in the skin, such as occurs with mycosis fungoides and the Sézary syndrome was discussed in Chapter 51.

Infiltration of the skin may occur in any of the leukemias or lymphomas, but is quite rare in MM. Leukemic infiltration of the skin was noted in 13% of our patients with AML, but in only 1% of those with ALL.<sup>1</sup> Although it has been suggested that skin infiltration is most frequent with monocytic leukemia,<sup>235</sup> this was not the case in our series.<sup>1</sup> Skin

infiltration may occur in patients with CLL and is least common in those with CML.<sup>235</sup> It complicates the course of approximately 5% of patients with HD or NHL.<sup>6,8</sup>

In AML, skin infiltrations are often diffuse, slightly raised, and dark reddish-brown to purple, although nodular lesions may occur (Fig. 54-17). In the other neoplastic diseases of the hematopoietic system, discrete intra- or subcutaneous nodules and plaques are more common. They may have the same color as the skin or appear erythematous. Ulceration of the overlying skin may occur (Fig. 54-18). The nodules may be painful, but more often are not, and diffuse infiltration may be associated with pruritus. Pruritus, as a symptom in HD, usually does not reflect skin infiltration (Chapter 50). On occasion, localized edema may surround infiltrates.

In the differential diagnosis of skin infiltrates, any other type of skin tumor as well as a variety of papular eruptions must be considered. If doubt exists regarding the na-

ture of the lesion, a small punch biopsy is advisable.

Systemic chemotherapy is indicated in most patients since skin infiltration is usually associated with widespread disease. However, local irradiation or even local application of chemotherapeutic agents (see Chapter 51) is effective. Treatment of noninfiltrative pruritus in HD and NHL should be directed at the primary disease, but some symptomatic relief has been reported with levomepromazine therapy.<sup>231</sup>

The term *leukemid* has been applied to the myriad of noninfiltrative forms of skin lesions associated with leukemia.<sup>1,235</sup> Severe skin diseases have been associated with leukemia and lymphoma and the association is unexplained. Examples include ichthyosis with severe anhydrosis,<sup>252</sup> erythema nodosum,<sup>311</sup> exfoliative dermatitis,<sup>222,325</sup> and pyoderma gangrenosum.<sup>310a</sup>

## Complications Due to Metabolic Imbalance

In any serious disease in which complex forms of therapy are employed, a wide variety of disturbances in fluid and electrolyte balance are to be anticipated. In this section we are concerned primarily with certain specific disturbances, such as hyperuricemia (page 1689) and hypercalcemia (page 1692), produced by the presence of hematopoietic neoplasms.

A negative nitrogen balance and weight loss commonly accompany all forms of leukemia, lymphoma, and myeloma. However, the degree of weight loss is quite variable and often is not a prominent feature in the leukemias, while, in contrast, in the terminal phases of HD many patients are cachectic. Anorexia, either due to disease or as a common side effect of many drugs (Chapter 55), is certainly a primary factor in inducing weight loss in many patients with leukemia, lymphoma, or myeloma. In extreme cases, intravenous hyperalimentation has been employed.<sup>423a</sup> The basal metabolic rate is abnormally high in many patients, even in the absence of fever.<sup>420</sup> Other studies of thyroid function usually give results that are within

Fig. 54-17. Myeloid leukemia of the skin (Ketron and Gay<sup>271a</sup> courtesy of the authors and Archives of Dermatology)

A

B

normal limits; the increased  $O_2$  utilization may reflect the growth requirements of the tumor cells. It seems possible that the increased  $O_2$  demands contribute to fatigue as well as to weight loss.

### Hyperuricemia

Hyperuricemia is a common manifestation that probably reflects an increased rate of purine metabolism due to rapid turnover of

the tumor cells. However, other factors, such as decreased plasma uricolytic,<sup>393</sup> may contribute to hyperuricemia. Abnormally high serum levels are common in untreated patients with AL or CML<sup>395,404,405</sup> as they are in those with polycythemia vera (Chapter 30) or idiopathic myelofibrosis (Chapter 57). Hyperuricemia is less common in untreated CLL, HD, NHL, or MM.<sup>395,404,416</sup> As one would expect, increased excretion of urate can be demonstrated in a greater proportion

# HYPERURICEMIA AND UREMIA ACCOMPANYING A RAPID DECREASE IN NUMBER OF BLASTS IN THE BLOOD WITH THERAPY

# HYPERURICEMIA AND UREMIA WITH A RELATIVELY STABLE NUMBER OF BLASTS IN THE BLOOD

of patients than can hyperuricemia.<sup>416</sup> Antitumor therapy leads to a sudden acceleration of purine breakdown and uric acid production. Hyperuricemic episodes in AL are shown in Figure 54-19.

# HYPERURICEMIA AND UREMIA WITH INCREASING NUMBERS OF BLASTS IN THE BLOOD

Fig 54-19. Hyperuricemia in acute leukemia (From Boggs et al.,<sup>1</sup> courtesy of the authors and Williams & Wilkins Company)

Gouty arthritis may occur but is not a particularly common complication. Gouty tophi are rarely, if ever, seen.<sup>424</sup> This may simply reflect the relatively short duration of hyperuricemia in leukemia and lymphoma as compared to that in idiopathic gout.

Urate nephropathy is a serious, but usually avoidable, complication of hyperuricemia that may develop when serum uric acid levels exceed 10 mg/dl. Any degree of renal failure in the presence of hyperuricemia should be considered presumptive evidence for urate nephropathy. The physicochemical properties of uric acid are important in the pathogenesis of urate nephropathy.<sup>260</sup> Ionized urate is much more soluble than the unionized form. The pK of uric acid is 5.4 so that, at normal blood pH, virtually all uric acid is ionized, but, at urine pH of less than 5.4, less than 50% is ionized. At normal blood pH, uric acid may remain ionized, even in supersaturated solution, explaining why serum urate concentrations in excess of saturation may be present without intravascular

crystal formation. However, the hyperosmolar, maximally acid distal tubules and proximal collecting ducts of the kidney provide an ideal milieu for precipitation of urate crystals. Urate nephropathy appears to be the direct result of precipitation of crystals in the distal tubules and collecting ducts with consequent mechanical obstruction. It may develop in untreated patients (Fig. 54-19) and may even be the presenting feature in AL,<sup>414</sup> but the degree of urate load required to induce this complication usually is associated with cytotoxic therapy. In this setting we have observed serum uric acid levels as high as 88 mg/dl.

Oliguria or, in severe cases, anuria develops and is accompanied by a rising BUN and all the accompanying features of acutely developing uremia. It has been suggested that extreme hyperuricemia in and of itself may produce anorexia, nausea and vomiting, lethargy and weakness since these symptoms have been observed to begin during uric acid nephropathy and before severe uremia had developed.<sup>421</sup>

Uric acid calculi may be formed and typical renal colic and, in some patients, ureteral obstruction may ensue.<sup>253</sup>

*Therapy of urate nephropathy rarely is necessary if proper attention is given to prevention of the complication. The use of allopurinol to reduce uric acid production prior to or concurrent with the initiation of cytotoxic therapy is a critical factor in preventing urate nephropathy.*<sup>395,405</sup> Allopurinol (4-hydroxyxypurazole[3,4-d]pyrimidine) is an isomer of hypoxanthine which inhibits xanthine oxidase. This enzyme is responsible for oxidation of hypoxanthine, converting it to xanthine and then to uric acid. Administration of 300 to 800 mg of allopurinol per day results in a significant reduction of serum and urinary uric acid and an increase in the oxypurines, hypoxanthine and xanthine, in urine.<sup>395,405</sup> For reasons yet to be determined, oxypurine excretion is not increased commensurate with the decrease in uric acid excretion, a factor which may be the primary reason for the usefulness of allopurinol in preventing nephropathy since the solubility

of oxypurines in the urine is similar to that of uric acid.<sup>405</sup> Indeed, on rare occasion, xanthine nephropathy may be associated with allopurinol therapy.<sup>399</sup> In addition to giving allopurinol, proper hydration, designed to produce increased urine flow and reduced osmolality of urine in the collecting ducts, is important. Alkalinization of urine by administration of sodium bicarbonate or acetazolamide is potentially useful, but is probably not necessary in prophylactic regimens.

If hyperuricemia is present at the time of diagnosis, it is wise to lower the serum uric acid by means of allopurinol and hyperhydration before giving cytotoxic drugs. This usually requires no more than two to three days and a therapeutic delay of this duration is rarely critical. The concurrent initiation of allopurinol with cytotoxic therapy in hyperuricemic patients may fail to prevent urate nephropathy.<sup>407</sup>

If this course is followed, urate nephropathy should be seen in only the occasional untreated patient whose tumor cell turnover rate is high enough to produce de novo nephropathy. However, oxypurine nephropathy should be anticipated occasionally.

The type of treatment for urate nephropathy depends, in part, upon whether the condition has progressed to the anuric stage. If oliguria is present, prompt but cautious hyperhydration is indicated, but excessive fluid should not be given. With oliguria, alkalinization of the urine with bicarbonate (100 mEq m<sup>2</sup>/24 hr) should be attempted.<sup>260</sup> Uricosuric agents should be avoided since reduced rather than increased<sup>122</sup> urinary uric acid is the goal. Allopurinol therapy, if not in use, should be instituted immediately. No form of antitumor therapy should be given during the period of urate nephropathy. In the anuric patient, as in any type of acute renal shutdown, the measures designed to carefully monitor and treat fluid and electrolyte balance are crucial. Diuresis induction with mannitol may be attempted, but if urine flow does not begin, repeated trials are not advisable.<sup>253</sup> Hemodialysis or peritoneal dialysis may be employed,<sup>389</sup> but usually is unnecessary. Spontaneous diuresis usually develops within a

week except in those who die from concurrent infection or hemorrhage.

Hypouricemia has been reported in HD and was apparently the result of a tubular defect resulting in excessive secretion of uric acid.<sup>392</sup>

### Hypercalcemia

Symptomatic hypercalcemia, common in MM (Chapter 52), may occur with any form of leukemia or lymphoma, but is not common.<sup>412</sup> Among these conditions it is probably most often seen in ALL,<sup>423</sup> and perhaps is least common in HD, CML, or CLL.<sup>401, 422</sup> Destructive bone lesions have been present in most patients and have been presumed to be the cause of the hypercalcemia,<sup>401</sup> but parathyroid infiltration has also been reported as a cause in AL.<sup>415</sup> Increased serum levels of parathormone were found in a child with AL in whom the parathyroids appeared normal at autopsy, suggesting that leukemic cells might be the source of the excess hormone.<sup>413</sup> Neither bone lesions nor excessive parathormone could be found in a patient with RCSa and hypercalcemia, but an extract of the tumor increased the serum calcium level when injected into mice.<sup>420a</sup> Although hypercalcemia has been a presenting feature of disease in ALL,<sup>406</sup> in most patients it has accompanied terminal or pre-terminal disease.<sup>401, 423</sup>

The array of symptoms and signs associated with hypercalcemia is almost limitless, but these usually can be divided into neurologic manifestations such as drowsiness, confusion, coma, and muscular weakness; gastrointestinal symptoms such as anorexia, nausea, and vomiting; renal disease with hyposthenuria and proteinuria; cardiac arrhythmias and other associated electrolyte disturbances such as hypokalemia.<sup>412</sup> Therapy should be directed toward alleviating the primary disease as well as toward lowering serum calcium per se. As discussed in Chapter 52, this includes various combinations of diuresis, phosphate loading, and therapy with adrenal corticosteroids and mithromycin.<sup>401</sup>

Unexplained hypocalcemia has been reported in ALL.<sup>422a</sup>

### Serum Proteins

*Albumin* levels in serum often are decreased in all of these diseases and tend to be decreased in direct proportion to the severity of the disease.<sup>394, 396</sup> (Fig. 54-3). In lymphoma, hypoalbuminemia usually reflects reduced rates of albumin synthesis or a shift of serum albumin into protein-rich effusions.<sup>426</sup> The cause of the reduced synthesis is unexplained.<sup>426</sup> Malnutrition, malabsorption, liver disease, diversion of nitrogenous precursors for tumor growth, and albumin loss in urine and from the bowel (page 1682) may contribute to the hypoalbuminemia.

Hypoalbuminemia may aggravate edema which results from lymphatic blockade or venous blockage (page 1679) and contributes to the accumulation of serous effusion (page 1678).

The *globulins* are often changed in concentration.<sup>394, 396</sup> Alpha-2 globulin is likely to be markedly elevated in HD (Chapter 50, Fig. 54-3). Nonspecific changes often are present in alpha-1, alpha-2, and beta globulins and the former two are frequently elevated when fever is present.<sup>32</sup> Changes in gamma globulins have been discussed (page 1654).

Cryoglobulinemia, of symptomatic degree, may complicate the course of AL and NHL as well as that of MM (Chapter 52). Cryofibrinogenemia has been reported in AML.<sup>398</sup>

Paraproteins may be observed occasionally in diseases other than myeloma, as discussed in Chapter 53. The hyperviscosity syndrome, which is associated with high serum paraprotein levels, has been discussed (Chapter 53).

*Other types of metabolic defects* abound, but their significance is unclear. Some examples will be given, but a complete survey is not intended. Urinary glycoproteins are increased in all forms of leukemia.<sup>425</sup>  $\beta$ -Amino-isobutyric acid, a metabolite not ordinarily found in urine, is present in some patients with any form of leukemia, but not in those with HD

or MM.<sup>403</sup> An increased excretion of 4-amino-5-imidazolecarboxamide was noted in patients with acute leukemia, but not in those with other hematologic neoplasms.<sup>408</sup> Levels of certain trace metals have been found to be altered in some patients; eg, low plasma magnesium was reported in a patient with HD, but high magnesium levels were found in the red cells of patients with acute leukemia. Nickel levels were increased or decreased in plasma and red cells in various patients; elevated plasma copper was found in some patients with HD, NHL, or leukemia, but chromium levels were consistently normal.<sup>402</sup> Plasma unesterified fatty acid concentration often is abnormally high and cholesterol is low in persons with hematologic malignant disease, as it is in persons with other forms of cancer.<sup>391,411</sup> Creatinine excretion was found to be decreased in all forms of leukemia, but creatine was increased in the urine.<sup>338</sup>

In AML patients,<sup>415</sup> false positive reactions to serologic tests for syphilis have been reported.

*Amyloidosis* is a common complication of MM (see Chapter 52) and, indeed, there is evidence to suggest that so-called "primary amyloidosis" may be a form of plasma cell dyscrasia.<sup>390</sup> This complication rarely is observed in leukemia or lymphoma, although it has been reported in lymphoma.<sup>291</sup>

## Pregnancy<sup>430</sup>

Pregnancy cannot be considered a "complication" of the diseases under discussion. Yet, a large body of literature is concerned with pregnancy developing during the course of these diseases and discusses the diagnosis of these diseases during pregnancy, at the time of delivery, or during the postpartum period. The frequency with which pregnancy has been reported to occur in women with various hematologic malignant conditions would appear to reflect the duration of survival associated with the tumor, the relative frequency of the tumor, and the age distribution of women with the tumor. Pregnancy

has been reported more often in women with HD or CML than in those with the acute leukemias.<sup>430</sup> Less frequent is pregnancy in women with NHL<sup>439</sup> and pregnancy is quite unusual in those having CLL<sup>432</sup> or MM,<sup>434</sup> diseases which are relatively rare in patients in the child-bearing age.

Three essential questions need to be approached in discussing the interrelation of pregnancy and hematologic malignant conditions: (1) What effect, if any, does pregnancy exert upon the tumor? (2) Does the tumor adversely affect pregnancy? (3) How does the interrelation of pregnancy and tumor influence therapy of the tumor?

The suggestion was raised that patients with AL or HD who become pregnant are more likely to improve spontaneously than nonpregnant patients.<sup>433</sup> This suggestion is not well documented and the opposite impression has been aired.<sup>436,451,456</sup> Pregnancy did not influence survival time of mice transplanted with a myeloid leukemia.<sup>444</sup> In general, it would appear that pregnancy has neither a salutary nor an adverse effect upon HD<sup>431,457</sup> or leukemia.<sup>430,441,443</sup>

The chance of delivering a full-term, healthy child is certainly reduced if AL is diagnosed during pregnancy.<sup>430</sup> This is less true in CML.<sup>430</sup> The possibly increased hazard of a child born of a leukemic mother developing leukemia has been discussed (Chapter 46). Transient pancytopenia has been recorded in a child born of a mother with untreated AML.<sup>442</sup> Maternal death from hemorrhage or infection at or shortly after delivery is not uncommon.<sup>430</sup>

The outcome of pregnancy occurring during HD and AL in remission or during the course of CML seems to depend primarily upon the type of therapy employed during pregnancy. Some antitumor drugs, such as methotrexate, are so efficient in inducing abortion that they have been used for this purpose.<sup>460</sup> Others, such as busulfan, used in relatively small doses in CML, have been employed during conception.<sup>462</sup> Normal infants have been delivered of mothers treated during the first trimester with 6-MP<sup>441,453</sup>

for acute leukemia; busulfan<sup>462</sup> and demecolcine<sup>447</sup> for CML; vinblastine,<sup>429,446</sup> nitrogen mustard,<sup>437</sup> and cyclophosphamide<sup>446</sup> for HD. However, severe congenital defects have been present in viable infants born of mothers treated for CML with busulfan and 6-MP<sup>458</sup> and for HD with alkylating agents.<sup>445,455</sup> In general, all antitumor therapy, with the possible exception of hormonal therapy, should be considered potentially mutagenic<sup>434, 438, 449, 450, 461</sup> and this consideration should influence the physician's advice and management of all pregnant patients with hematologic malignant disease.

Thus, a general statement can be made to the effect that the hematologic neoplasm adversely affects pregnancy, but does not clearly dictate its interruption; pregnancy does not clearly influence the course of the neoplasm in any fashion; but therapy of the neoplasm is complicated by the presence of pregnancy. These considerations lead to certain practical recommendations, as outlined below.

If NHL or CML is diagnosed during pregnancy, therapy should be withheld in most of these patients since cure is not anticipated and there is no evidence that a delay in therapy will reduce survival unless unusual complications are present (Chapters 49 and 51). In the rare circumstance of pregnancy during CLL or MM, the same considerations may be applied. If AL is diagnosed, the average survival of untreated patients does not exceed three months (Chapter 47). Thus, antitumor therapy should be undertaken unless pregnancy is very near to termination. Abortion will often follow antileukemic therapy undertaken during the first or even the second trimester.<sup>452</sup> Perhaps the most difficult decision concerns the patient in whom a diagnosis of HD is made during pregnancy.<sup>6</sup>

The first situation that can be posed is that of the patient in whom HD has been diagnosed, clinical staging has been completed (Chapter 50), and pregnancy is discovered before therapy has begun. If the disease is limited to areas above the diaphragm and is stage I or II-A, radiotherapy to involved nodes only might be given as a temporizing measure.<sup>6</sup> However, if more extensive disease

is present, requiring immediate extensive irradiation or chemotherapy in order to enhance the chances of cure, abortion should be recommended. Radiation therapy to the groin or even to the entire mediastinum probably entails appreciable risk to the fetus from radiation scatter, even when careful collimation of beams is attempted.<sup>435</sup> When HD is discovered during pregnancy, therapeutic abortion or cesarean delivery, if the fetus is potentially viable, may be advisable in order to permit clinical staging and definitive treatment.<sup>6</sup> In all cases, it must be recognized that if the mother chooses not to be aborted, then the physician must still design the best form of treatment that is consistent with the delivery of a completely healthy infant.

If pregnancy coincides with relapse of HD when cure of disease is no longer likely, further therapy often can be delayed until after delivery.

Other Forms of Therapy

Development of New Agents

THE principles underlying the use of radiotherapy, chemotherapy, or other modalities of treatment are the same for all types of hematologic malignant diseases but details concerning their use differ, as discussed in Chapters 47 to 53. In this chapter the general principles of therapy, the mechanism of action of each useful form of therapy, and the associated toxicity are considered. The treatment of complications was discussed in Chapter 54.

## **Approach to the Patient with a Proven Hematologic Neoplasm**

It is important to develop a specific plan of therapy for each patient, taking into account the nature of the tumor, its natural

course if left untreated, whether cure is feasible, and also such variables as age, psychologic aspects, economic status, coexisting diseases, and the presence or absence of complications associated with the tumor.

The importance of distinguishing between *therapy with curative intent* and *palliative therapy* for each disease has been discussed previously, but deserves reemphasis. Cure is a practical therapeutic objective in most patients with Hodgkin's disease (Chapter 50) and in certain patients with non-Hodgkin's lymphoma (NHL) (Chapter 51), even if the goal is not attained. With presently available forms of therapy, cure is not a reasonable possibility in the *chronic leukemias* (Chapters 48 and 49), in acute myeloblastic leukemia (Chapter 47), in multiple myeloma (Chapter 52) and in other protein-secreting tumors (Chapter 53), or in most patients with NHL. The dilemma of whether acute lymphoblastic leukemia should or should not be approached routinely with intent to cure has been discussed (Chapter 47). Continuing attempts to cure patients with these diseases by experimental forms of therapy are exceedingly important, but until evidence is forthcoming that cure is possible, palliative therapy remains the treatment of choice for patients who have not volunteered for studies in research institutions.

The goal of palliative therapy is simple to state but frequently difficult to achieve. This is to keep the patient's physical and emotional health as optimal as possible for as long as possible. If cure is not possible by presently available means, if the patient is asymptomatic, and if the known natural course of most patients with the disease suggests that the patient is likely to remain asymptomatic for some time, it is usually best to give no antitumor therapy. Watchful waiting is particularly useful in the management of many patients with chronic lymphocytic leukemia. In other circumstances, therapy may be advisable in an asymptomatic patient because the natural course of the disease is such that the asymptomatic period will be terminated shortly unless therapy is given. For example, the patient with CML who is beginning to

relapse from busulfan-induced remission is likely to benefit from re-treatment with busulfan and nothing is gained by waiting for florid relapse to develop.

If cure is the goal, and if iatrogenic complications must be induced to attain that goal, even life-threatening toxicity may be acceptable. Conversely, if palliation is the goal, attention to the relative toxicity of various therapeutic regimens becomes especially important, and the least potentially toxic therapeutic agent should be chosen.

The physician also should consider the relative expense of various forms of palliative therapy because he should attempt to avoid superimposing "medical indigency" in an already troubled family. This entails less the actual cost of drugs than it does the frequency of hospitalization, office visits, and laboratory and radiologic procedures required by various regimens.

The age of the patient and the presence of other diseases must also be considered. In the opinion of some, radical radiotherapy either should not be carried out or should at least be modified in the elderly.<sup>96</sup> The reduced remission rate in elderly patients with AML appears to reflect increased drug toxicity primarily (Chapter 47), which suggests that less aggressive therapy should be employed in the aged than in younger patients.

The physician must be willing to deal with and care for all needs of the patient, most particularly the *psychologic problems* posed by *potentially fatal disease*. The physician who refuses to acquaint his patient with the diagnosis of a hematologic malignant disease may be protecting himself, rather than his patient, from emotional trauma. Only rarely are the circumstances such that informing the patient is best avoided. A patient who must undergo the type of therapy employed realizes that the disease is serious. Unless he has meaningful knowledge of his disease, a distressing syndrome may develop; he knows that he is seriously ill, but realizes that his family (and physician) do not want to talk about it. As a result, he is denied the emotional support of full and frank discussion and is isolated from meaningful communication with his

loved ones at a time when he most needs it. *However, the discouraging information should be presented as kindly as possible, even though it should be truthful.* Certain studies<sup>177</sup> suggest that teenagers and even younger children are relieved by acknowledgement of the diagnosis and discussion of its implications. The responsibility imposed upon the physician in informing the patient is considerable, but must be accepted. In most instances the hematologist is a consultant who has had no previous acquaintance with the patient or his family. Consequently, he is faced with communicating information to a person with whom he is, at best, minimally acquainted.

One must determine, by subtle clues, when the patient wants to talk about his disease. Often the patient will take the initiative by asking the physician if a diagnosis has been made. If the physician answers in the affirmative, but then counters by inquiring what the patient thinks his disease is, it is surprising how frequently the patient will reply that he thinks he has leukemia. Thus, the barrier is broken.

Leukemia carries a greater reputation as a "dreaded disease" than do other forms of hematologic malignant disease, probably because of the prognosis associated in the minds of laymen with the acute leukemias. If the diagnosis is leukemia, it is wise to determine what the patient knows about leukemia. If the diagnosis is anything other than AML, the physician then can explain that there are various types of leukemia, that prognosis differs with each, and that the patient does not have one of the worse varieties. Conversely, if enlarged lymph nodes are due to HD or other lymphomas, it should be explained that the patient does not have leukemia, but rather has a tumor of lymph nodes. The patient often wants to know if his disease is a cancer. Most patients and many physicians equate cancer with carcinoma and it is wise to explain that while some consider the lymphomas to be a form of malignancy, their behavior and their therapy are quite different from those of other forms of cancer. These types of interchanges provide the background against which one

can go on to discuss the many problems posed by the disease and its management.

Whether there is a reasonable chance of cure should be discussed realistically. That there may be a slight chance of cure should never be completely ruled out in discussion with the patient; there is no malignant neoplastic disease, no matter how extensive, in which apparent recovery has not been reported although recovery may be an extremely remote possibility. Thus, with stage I, II, or even III HD, cure following extensive therapy should be presented as probable, but by no means certain; while, with AML, cure can be presented as quite unlikely, but not impossible. Such a discussion is by no means in contradiction with the physician's therapeutic approach (page 1703) and allows the patient to retain hope.

It is unwise to tell the patient anything concerning average survival rates for his disease. Such averages are valuable to the physician in comparing different modes of therapy, but are derived from data that have such a wide or skewed distribution that they have little meaning with reference to the individual patient. It is not dishonest to mention one's long survivors with the disease in question, as long as one is careful to emphasize that similar survival is a possibility and not an expectation. If patients maintain some hope, their outlook usually is more optimistic and their life becomes more rewarding than when they are led to regard their diagnosis as a death sentence with finite limits and no hope.

The physician must be prepared not only to discuss all aspects of the patient's disease, but must stimulate the patient to hold free and frank discussions with him. It is helpful for the physician to encourage the patient repeatedly to ask questions no matter how trivial the questions seem to be. Most commonly, the patient is concerned about what changes in his usual life are necessary. Since there is no good evidence that diet, drink, or physical and other accustomed activities modify the course of any of the diseases under consideration, the best advice to give the patient is: "Lead as normal a life as possible and do what you feel like doing." This

requires repetition to be believed. It is also advisable to warn the patient that relatives, friends, and neighbors are likely to give well-meant, but often faulty, advice. In general it is best to limit the number of friends and associates who are informed about the diagnosis. Although there are patients who transfer transiently or permanently to the "cancer quacks," the frequency of such transfer is markedly reduced if free and frank discussion with the patient and his close relatives is practiced.

With regard to therapy, it is important to explain what the goals are—curative or palliative. Similarly, patients should be warned concerning the side effects of the drugs used and the complications of their disease, without being led to expect that any or all of these will occur. If patients feel free to call their physician when they are concerned about a problem, proper care is facilitated. If the concern is minor, reassurance relieves the patient and conserves the physician's time. If the problem is of importance (ie, development of fever in CLL), prompt diagnosis is facilitated and the well-being of the patient and the effectiveness of the physician are enhanced.

It is of value to discuss research concerning the cause and treatment of the disease with the patient. Hope for a cure of the incurable is an important ingredient and such hope can be justified by on-going research. If the patient can be assured, truthfully, that his physician will be aware of any new developments relating to his disease, some degree of comfort is provided and the exaggerated reports of new forms of therapy that reach the news media are more easily explained.

The death of a child is particularly traumatic psychologically<sup>24</sup> and much care and counseling must be provided the patient and the parents of children with leukemia and other tumors.<sup>54</sup>

In summary, the physician must deal with the patient and the patient's family individually rather than as another "case." If he cannot cure, he must at least bring all his skills to bear to provide comfort.

Prolonging misery as compared to prolonging enjoyable life is a subject that is often

discussed by thoughtful physicians, but is rarely considered in print in a realistic fashion. The physician often realizes that, in all of the diseases under discussion, a stage is reached ultimately when there is little chance of helping the patient to achieve any degree of comfortable life. Yet, by means of various drugs and complicated life support systems he knows that he can probably sustain a semblance of life for days, weeks, or even months. There are physicians who believe that life must be sustained for as long as possible under any circumstance. Others, such as ourselves, think that the long-continued absence of some degree of comfort and ordinary enjoyment of life ceases to meet the definition of life. Positive acts to terminate life in such circumstances constitute euthanasia, but failure to act with therapeutic vigor is a different matter. With respect to the failure to react vigorously to an apparently hopeless situation, the accord, often unspoken, reached between physician, patient, and patient's family often is remarkable. However, the physician bears the responsibility for reaching a decision as to whether or not to use every possible means to maintain the patient's life for a few more days and cannot put the burden of this decision solely on the family. When a firm decision to resist further therapy has been reached by a patient, the widely variable psychologic reactions of members of the medical staff may interfere with their ability to serve the best interests of the patient.<sup>155</sup> And lastly, the dignity of the patient must be respected and the trauma to his loved ones caused by the sight of a body entrapped by tubes and other disagreeable equipment must be avoided unless something really worthwhile is to be gained by use of such devices.

### Agents Useful in the Treatment of Hematologic Neoplasms<sup>122,123,153,197</sup>

**HISTORY.** Unlike most forms of carcinoma, *surgical excision* has never played a prominent role in the therapy of the leukemias, lymphomas, or myelomas. As discussed in Chapters

50 and 51, surgical removal of local foci of HD or NHL has resulted in occasional apparent cures, but extensive dissection and removal of diseased tissue has not proved to be of benefit. Early enthusiasm (1900-1910) for cure of HD by radiotherapy<sup>93</sup> was followed by a half century of pessimism; radiotherapy came to be considered a useful palliative procedure, but in no sense a curative measure. With technical improvements, radiotherapy has been reaffirmed as potentially curative (see Chapter 50). Similarly, when the first complete remissions were induced with antifolic acid chemotherapy in AL in 1947-1948, the hope that these antimetabolites were curative was quickly negated by rapid relapse of disease. Modes of therapy developed subsequently, such as use of asparaginase, have been associated with similar phases of initial enthusiasm followed by discouragement. Ultimately, however, apparent consistent cure of a tumor by chemotherapy was demonstrated by the use of toxic doses of methotrexate in choriocarcinoma. That this tumor, which contains non-host tissue (male contribution to gene constitution), was curable by chemotherapy did much to establish the validity of nonsyngeneic animal tumor transplant systems as models for nonsyngeneic tumors. At the same time, the fact that most human tumors arise strictly from the host raised doubt concerning the validity of transplanted, nonsyngeneic tumors in animals as models for the evaluation of chemotherapeutic agents.<sup>163</sup> However, the cure of syngeneic human tumors by chemotherapy appears to have been accomplished in a significant number of patients with Burkitt's lymphoma (Chapter 51) and perhaps in those with HD (Chapter 50).

### Classes of Antitumor Agents

The physical agents that are of general usefulness as antitumor agents are x- and gamma-irradiation, but beta- and electron-beam irradiation also are of potential benefit. These and the chemotherapeutic agents that are of proven value in the treatment of the hematologic malignant diseases are listed in Table 55-1.

**Table 55-1. Agents Useful in Therapy of Hematologic Malignant Diseases**

Agent	Non-Cell-Cycle Dependent	Cell-Cycle* Dependent
Irradiation		
X-rays	✓	
γ-rays	✓

Miscellaneous agents		
L-Asparaginase	✓	
Procarbazine	✓	
Nitrosoureas		✓?
Dibromomantrol	✓?	

\*The drugs listed in this column are more effective in a particular stage of the cell cycle than in another. Nevertheless, the action of all agents may be cycle dependent to some degree.

The effectiveness of physical and chemotherapeutic agents in killing tumor cells depends, at least in part, on what stage in the generative cycle of cell growth most of the tumor cells are to be found. As discussed in Chapter 2, the generative (G) cycle can be divided into G<sub>0</sub>, G<sub>1</sub>, S, G<sub>2</sub>, and M phases. Cells in G<sub>1</sub> will progress within a finite time into DNA synthesis (S), then to G<sub>2</sub>, and then divide by mitosis (M). Thus, cells in G<sub>1</sub>, S, G<sub>2</sub>, and M constitute the proliferative compartment. Cells in G<sub>0</sub> are nonproliferating, but can be stimulated to enter G<sub>1</sub> by appropriate, but poorly defined, stimuli. A classification of chemotherapeutic agents as "cycle dependent," or not, is useful in applying cell kinetic considerations in the design of therapeutic regimens (page 1709).

Agents that are "cycle dependent" are those that do not kill cells in  $G_1$  or  $G_0$ , but selectively kill cells in S or M. Noncycle-dependent agents are those that kill in  $G_1$  or  $G_0$  (interphase death) as well as in S,  $G_2$ , or M. This distinction, however, is not sharp. Thus, some noncycle-dependent drugs have a greater effect on cells in cycle than on those in interphase (cyclophosphamide<sup>176</sup>), whereas others may be less effective on cells in S and  $G_2$  than in other phases of the cycle (HN2<sup>9</sup>).

The diseases in which each of the various drugs has been shown to be beneficial are summarized in Table 55-2. Detailed recommendations regarding the use of these agents

will be found in Chapters 47 to 53. It is evident that no single agent is of benefit in all diseases and that no disease is modified beneficially by all available agents (Table 55-2).

The *ideal drug* is one that kills tumor cells, but has no effect on normal cells. While no such agent has been found, significantly greater killing of tumor as compared to normal cells is exhibited by four agents: steroids, asparaginase, vincristine, and bleomycin. Other agents may have a slightly greater effect upon tumor cells than upon normal tissue, but their tumor-killing effects are more dependent upon differences in the ki-

netics of recovery of tumor and of normal cell populations than on their less damaging effect on normal cells (see below).

### Normal and Tumor Cell Kinetics as Related to Antitumor Therapy

At one time it was assumed that tumors grow more rapidly than do comparable normal tissues. As regards neoplastic disease of hematopoietic tissue, this hypothesis has been

largely disproved; eg, in the acute leukemias or in CML, the generation time for the average potentially dividing cell tends to be longer than normal<sup>167,98,112,123</sup> (also see Chapter 46). Consequently, even if normal hematopoietic cells are killed to the same extent as tumor cells, recovery of normal cells will be faster (Fig. 55-1). This idealized concept of tumor cell kill is based on the extensive studies of investigators such as Skipper and colleagues in murine systems.<sup>160,162,163</sup>

Fig 55-1. Differential effect of a noncycle-active drug on normal hematopoiesis and on tumor cells based on differences in growth rate of the two systems. Tumor growth rate is slower than that of normal hematopoietic tissue so that while each dose of a drug (or irradiation) will destroy an equal proportion of the total cell mass, tumor size is progressively reduced (From Boggs and Chervenick,<sup>20</sup> courtesy of the authors and Grune & Stratton)

A fixed percentage of a sensitive cell population is killed by each dose of a drug or physical agent.<sup>78</sup> With noncycle-dependent agents the percentage of the population killed increases as the dose of the agent is increased so that exponential killing is observed. The classic model for this type of cell kill is irradiation (Fig. 55-2). With cycle-dependent drugs, only that segment of the cell population that is in the sensitive phase of the cycle is affected. Thus, when drugs such as methotrexate or cytosine arabinoside are given to patients in whom a limited proportion of the population of tumor cells is in cycle, a plateau of killing is reached (Fig. 55-3). Current data on tumors in man, such as ALL,<sup>112,129</sup> suggest that most of the tumor cell population is in  $G_0$  or in a prolonged  $G_1$ . Thus, most of the population is not affected by a single

dose of a cycle-dependent agent; repeated therapy is required. As a portion of the compartment is killed with each dose, it is assumed that recruitment into cycle is induced in the residual population, making more cells available for the action of the drug (Fig. 55-4). The use of specific cycle active drugs at a time when cells are wholly or partially synchronized in the sensitive phase of the cycle may lead to distinct improvement in the therapeutic efficiency of such drugs.<sup>101</sup>

From such kinetic considerations the concept of "total cell kill" as a therapeutic approach has arisen; this concept is similar to that of the surgical approach of total excision of tumor tissue. In murine transplanted tumor systems, in which an accurate measure of the total number of tumor cells in the host can be obtained, killing curves resulting in

Fig 55-2. Effect of increasing doses of a noncycle-active agent (whole-body irradiation) on the number of endogenous murine hematopoietic spleen colonies. Each colony represents the survival of a pluripotential hematopoietic stem cell. The killing of such cells is an exponential function of dose. (Courtesy of SS Boggs.)

Fig 55-3. Effect of increasing doses of a cycle-active agent (cytosine arabinoside) on transplanted spleen colony-forming cells. Each colony represents the survival of a pluripotential hematopoietic stem cell. As the dose is increased, a plateau of killing results, indicating that most of the cell population is in a long  $G_1$  or in  $G_0$ . (Courtesy of SS Bogggs)

total cell kill have been published.<sup>163</sup> In human tumors the total number of tumor cells at the start of therapy cannot be measured and, while calculations have been made, particularly in ALL,<sup>84</sup> the number of assumptions involved in such calculations is so large that their accuracy is doubtful. However, accomplishment of total cell kill in human tumors in certain circumstances is suggested by indirect evidence. For example, in HD, the chance of recurrence in an irradiated area is a negative exponential function of the irradiation dose delivered to that area (see Chapter 50). The probability of total cell kill in an exponential killing system can approach, but never reach, 100%.

Ideally, one would like to test the patient's

tumor cells against a variety of agents in an *in vitro* system, thereby predicting the most effective agent for each patient.<sup>40</sup> However, this desirable goal has yet to be attained.

#### Interaction of Various Therapeutic Agents

Cross resistance and possible antagonism between agents are important concepts to consider in choosing the best form of therapy for each patient.

Cross resistance has been demonstrated clearly for a number of agents (Table 55-3)<sup>164</sup> and certain generalizations seem justified. The patient who is not or is no longer responsive to one alkylating agent is unlikely

Fig 55-4 Effect of repeated doses of a cycle-dependent agent on killing of lymphoblasts in leukemia and recruitment into cycle from  $G_0$ . With each dose the compartment is reduced by the number of cells that were in the sensitive phase of the cycle and in response to compartment depletion, a greater proportion comes into cycle after each dose. This somewhat idealized figure is derived from studies such as those of Lampkin et al.<sup>112</sup>

to be responsive to another alkylating agent. Similarly, resistance to one of a class of closely related agents would imply resistance to another in that specific group; it seems likely that resistance to 6-MP implies resistance to similar purine analogs and that resistance to methotrexate implies resistance to all other compounds that act as inhibitors of folic acid. Conversely, there is no evidence

for significant antagonism within a class of agents. For example, in ALL there is abundant evidence that initial response to one agent, such as methotrexate, does not reduce the likelihood of subsequent response to another agent such as 6-MP (Chapter 47).

Neither synergism nor antagonism has been shown between drugs in any tumor system in man, but the absence of such evi-

**Table 55-3. Cross Resistance of Chemotherapeutic Agents**

<i>Agent Useful in Treatment of Hematologic Neoplasm</i>	<i>If Resistance to Agent Develops, Resistance to the Following Agent is Expected*</i>
Adrenal glucocorticosteroids	None

6-Mercaptopurine	Thioguanine, azaguanine
Vincristine	Vinblastine
Asparaginase	None
Procarbazine	Unknown
Hydroxyurea	Unknown

\*This list is limited to instances of proven cross resistance. The absence of an agent from the list does not mean that cross resistance does not occur. Adapted from Skipper et al.<sup>144</sup>

dence does not deny this occurrence, since direct measurement of the number of cells killed has not been possible. Indirect evidence, such as rate of remission in acute leukemia, is the only available criterion. Examination of the results of clinical trials of drugs used in combination for inducing remission in ALL, as compared to predicted responses if the effects of the drugs were simply additive in their action, fails to suggest either synergism or antagonism in the aggregate (Table 55-4). One might suggest that synergism is present between daunomycin and prednisone and that there is antagonism between 6-mercaptopurine and methotrexate. However, favorable or unfavorable modification of toxicity is as reasonable an explanation for the differences in the observed effects as is synergism or antagonism. Furthermore, the identity of the average figures of predicted and observed values for all combina-

**Table 55-4. Synergism or Antagonism between Antitumor Agents in Inducing Remission in Acute Lymphoblastic Leukemia**

<i>Average Response to Single Agents*</i>		<i>Predicted Additive Response to Combination†</i>	<i>Observed Response*</i>
Prednisone	69%	91%	89%

Vincristine	72%		
6-Mercaptopurine	60%	84%	84%
Methotrexate	25%		
Total Average			

\*Data from Table 47-6, complete plus partial remission

†Calculated with the assumption that each drug acts in an additive fashion and affects an independent proportion of the population, the probability of not responding to one drug was multiplied by the probability of not responding to another. For example, the probability of not responding to prednisone is 0.31, for vincristine, 0.28, and the probability of responding to neither is 0.09.

tions examined suggests that drugs used in combination act in a simple additive fashion (Table 55-4).

### Hematopoietic Toxicity of Antitumor Agents

There are significant differences in the toxic manifestations of all of the agents used in the treatment of hematologic malignancies. The toxic effects of each agent, whether dose related or idiosyncratic, will be discussed subsequently. However, it is the dose-related effects of most agents upon the normal hematopoietic system which constitute the most common toxic manifestations that require interruption or modification of therapy. Other toxic effects may be just as common but not as easily detected, eg, reversible aspermia or oligospermia has been noted following chemotherapy of AL<sup>155a</sup> and lymphoma<sup>159a</sup> and after irradiation in HD.<sup>166a</sup> This is true of all agents except for prednisone and bleomycin, which appear to be free from hematopoietic toxicity, and vincristine and asparaginase, which have no such toxicity in most patients but induce severe hematopoietic depression in a few.

No significant direct effect is observed on mature cells of the blood or upon the post-mitotic compartments of the marrow, with the possible exception of such subtle effects as reduced phagocytic killing by neutrophils exposed to x-irradiation.<sup>157</sup> It is the proliferating and potentially proliferating marrow precursors of neutrophils, platelets, and erythrocytes, as well as those of the immune system (lymphocytes), that are affected. Consequently, knowledge of normal cell kinetics, as outlined in earlier chapters, is important in predicting and understanding hematopoietic toxicity, particularly in its recognition by the examination of changes in blood cells.

From studies in the mouse,<sup>19,20</sup> it is assumed that the pluripotential hematopoietic stem cell compartment, which gives rise to the myeloid elements, is normally a cell compartment primarily composed of noncycling cells. Consequently, cycle-dependent drugs have less effect on this compartment than do

noncycle-dependent drugs. There is evidence in the mouse to suggest that busulfan damages the pluripotential stem cell compartment to a greater degree than it does the more mature compartments.<sup>19</sup>

Thus, certain predictions can be made concerning hematopoietic toxicity, as reflected in blood values for single (Fig. 55-5) or repeated (Fig. 55-6) doses of chemotherapeutic agents.

A single dose of an agent that destroys all hematopoietic cell production, ie, a potentially lethal dose of whole-body irradiation or cyclophosphamide, spares only mature and post-mitotic maturing cells of the blood and marrow. Thus, following administration of such an agent, blood values would reflect storage pools of cells and cell life span only. In the case of platelets, for which little or no storage reservoir exists (Chapter 9), the number of these cells in the blood would decline steadily and the cells would disappear in approximately 10 days—the limit of platelet life span (Fig. 55-5). Neutrophils would be maintained in normal concentration until the post-mitotic storage and maturation pool of the marrow is exhausted (approximately 10 days) (Chapter 6); then their concentration would fall precipitously owing to their short intravascular sojourn (Fig. 55-5). In contrast, the long life span of erythrocytes allows near normal values to be maintained beyond the time when severe neutropenia and thrombocytopenia have developed. In treating a patient, the onset of cytopenia can be expected to be earlier than depicted in Figure 55-5 since the patient's disease may have modified the system so that the neutrophil storage pool is reduced while treatment and infection may have induced inflammation, resulting in increased cell utilization.

In contrast to a drug that destroys recognized mitotic compartments as well as noncycling stem cell compartments (Fig. 55-5), a single dose of a cycle-active agent may destroy all recognized mitotic compartments, but the noncycling stem cell compartment is spared. In such instance, the marrow can regenerate and begin to replace mature cells before complete pancytopenia has been induced.

Fig 55-5. Effects of a potentially fatal dose of a drug on blood cell level and marrow production. With a potentially lethal dose, recovery of the stem cell and of the mitotic compartments is delayed so long that severe pancytopenia occurs. Rate of loss of mature and maturing post-mitotic cells is based on normal cell kinetics as reviewed in Chapters 5, 6, and 9 (Schematic)

However, chemotherapeutic drugs are not ordinarily administered in single doses. The effect on neutrophils, platelets, erythrocytes, and stem cells of regularly repeated doses is much more complex than that of single doses. The action of repeated doses of a DNA-inhibiting cycle-active agent upon the stem cell system, the marrow mitotic pool, the marrow storage pool, and the blood neutrophil compartment is shown in Figure 55-6.

The postulated dose of drug is the amount that is sufficient to destroy any cells that are in DNA synthesis. It is assumed that DNA synthesis accounts for one half the cycle.

With the first dose, the stem cell compartment is reduced only very slightly, since only a small proportion is in DNA synthesis. The marrow mitotic pool is reduced by half, since half of it is in DNA synthesis. Neither the marrow storage pool nor the blood is imme-

Fig 55-6 Effects of repeated doses of a cycle-active agent on neutrophils in the blood and in the marrow storage compartment and upon stem cell and recognized mitotic compartments. See text for further description. (From Boggs and Chervenick<sup>20</sup> courtesy of the authors and Grune & Stratton.)

diately affected. By the time the second dose is administered, the stem cell pool has hypertrophied slightly in response to the damage in the more mature compartments; half of it is now in DNA synthesis, and with the second dose half of it is destroyed. Again the marrow mitotic pool is reduced by half, and, since it had not fully regenerated, it is smaller than after the first dose. The marrow storage pool again is not affected by the second dose, but is smaller than normal because of reduced feed-in from the marrow mitotic pool and continued output to the blood. Since significant storage remains, the blood has not been affected. By the time the third dose is given, some regeneration has occurred in the stem cell compartment, but the stem cell pool has not returned to normal and half is still in DNA synthesis. Therefore, it is again reduced by half and the same is true for the marrow mitotic pool. Again, because of continued normal feed-in to the blood and subnormal feed-in from the marrow mitotic pool, the marrow storage pool is further reduced and is now rather small. However, it is still maintaining the blood pool at a near-normal size. By the time the next dose is due,

disaster has struck. There is severe neutropenia because the storage pool has become completely exhausted and feed-in into the blood has been markedly reduced.

It seems reasonable to assume that delayed and somewhat unpredictable hematopoietic toxicity associated with drugs such as BCNU (page 1730) reflects a selective damaging effect of the drugs on resting hematopoietic stem cells.

It must be emphasized that changes in numbers of blood cells lag significantly behind changes in the precursor compartments that are the sites of action of antitumor agents. Thus, while we use the blood cell level as a guide to hematopoietic toxicity, we must recognize that toxicity is already relatively severe when changes in the numbers of blood cells are evident.

In addition to quantitative changes in blood cells, qualitative morphologic changes frequently are produced. Megaloblastosis is commonly observed; drugs that selectively affect DNA synthesis, such as methotrexate, 6-MP, and cytosine arabinoside, frequently are associated with the appearance of megaloblasts. The general mechanism is presumably

the same as that resulting in megaloblastosis in  $B_{12}$  and folate deficiency (Chapter 14); nuclear (DNA) synthesis is retarded in growing cells, while synthesis of cytoplasmic constituents is affected to a lesser degree or not at all.

As noted in Chapter 54, therapy may cause suppression of immune function. When intensive therapy of ALL was stopped, repopulation of lymphoid tissues was found to occur more rapidly in younger than in older children.<sup>25a</sup>

## Specific Antitumor Agents

The following discussion of the dosage, route of administration, mechanism of action and toxicity of agents useful in treating hematologic neoplasms is necessarily brief. More detailed discussions will be found in published reviews.<sup>29,34,122,123,153,197</sup>

### Radiotherapy<sup>96</sup>

In 1902, shortly following the discovery of x rays, Pusey<sup>148</sup> described the usefulness of these rays in treating patients with HD and those with other lymphomas. The value of x rays and the closely related gamma and beta rays emitted by various radioisotopes has been amply confirmed.

The dose of radiation delivered to a tumor or to surrounding normal tissue is best measured in rads rather than in roentgens. "Rad" refers to the actual absorbed dose in tissue, while "roentgen" is a measure of ionization in air. The effective dose of x rays not only depends upon the number of rads delivered to tissue, but also upon the rate of delivery. The rate of delivery and the penetrance of the x rays are functions of the energy (voltage) of x-ray machines and the type of filtration to which the generated beam is subjected. Modern radiotherapy machines operate in megavoltage ranges and have almost entirely supplanted kilovoltage equipment for most purposes in most treatment centers. Van de Graeff electrostatic generators of x rays have a peak energy of approximately 2 million electron volts (MeV); radioactive

cobalt teletherapy units emit gamma rays with energy equivalent to 3 MeV, and linear electron accelerators and betatrons, machines capable of generating either gamma or x rays, provide x-ray beams with as high as 8 and 40 MeV, respectively.

Selection of the desired total tumor dose and of its delivery time is empiric and, as was discussed in Chapter 50, depends in large part upon whether the therapeutic intention is curative or palliative. Thus, 4000 rads delivered within four to six weeks may be desirable in radical radiotherapy of HD (Chapter 50), 2400 rads is a desirable total dose to the craniospinal axis as prophylaxis against development of CNS leukemia (Chapter 54), while doses of only 400 to 600 rads to the spleen of patients with CML may produce the desired effect (Chapter 48). Optimal dose schedule with respect to dose fractionation has not been clarified for any human tumor.<sup>53</sup>

X rays or gamma rays generated by megavoltage equipment are highly penetrant and low-energy beams generated by such equipment can be largely eliminated by placing filters of copper or aluminum in their paths. Thus, deep-seated tumors can be treated with high doses without inducing intolerable damage to overlying tissues such as the skin; such damage was the primary dose-limiting factor with kilovoltage equipment.

Shielding of normal tissue, treatment of large fields to avoid the problem of calculating doses delivered to areas overlapped by small fields, and a variety of important technical aspects of radiotherapy are crucial considerations in the proper use of radiotherapy.<sup>96</sup>

Radioactive isotopes may be used as external sources of irradiation in machines in which cobalt ( $^{60}\text{Co}$ ) or cesium ( $^{137}\text{Cs}$ ) constitute the energy source. They may be injected into the patient as localized implants of radium or may be given systemically with the knowledge that the isotope tends to localize in certain areas. Thus, radioactive sodium phosphate ( $^{32}\text{P}$ ) localizes in bone marrow, colloidal radioactive gold in the reticulo-endothelial system, and radioactive strontium in bone.

The gamma rays emitted by isotopes such as  $^{32}\text{P}$  have limited penetrance and their beta rays even less. Thus, irradiation is confined to a very limited area surrounding the site of lodgement of the administered isotope. In therapy with  $^{32}\text{P}$ , most of the isotope is incorporated into dividing hematopoietic cells and production in this compartment is reduced with minimal radiation damage occurring in other tissues. Although this isotope has found some use in treating CLL and CML (Chapters 48 and 49) its most common use has been in the treatment of polycythemia vera (Chapter 30).

Other low-energy rays include *electron beams*, whose low penetrance makes them useful in treating skin diseases such as mycosis fungoides (Chapter 51).

### *Effect of Ionizing Radiation on Cells*<sup>7,24,25,53,96,115</sup>

Ionizations resulting from the passage of x or gamma rays, or charged particles, through or into cells may lead to disruption of biologically important macromolecules either directly or by production of free radicals. These free radicals are exceedingly unstable molecules with unpaired electrons and, thus, can combine with and damage or inhibit normal cellular constituents.<sup>69</sup> The events that follow depend on the total number of ionizations (dose), rate of ionization (dose rate), type of cell, phase of cell cycle, and ability of the cell to repair or replace damaged molecules. The unrepaired damage may result in instant death of the cell during irradiation (about 100,000 rads) together with gross alterations of the chemical machinery of the cell with coagulation of proteins and depolymerization of DNA. With much smaller doses (100 to 1000 rads), death is delayed. Delayed death may occur in interphase before and independent of DNA synthesis or mitosis, during DNA synthesis or mitosis, or after one or more mitoses have occurred. Permanent inhibition or severe retardation of mitosis, with the cell surviving but productively dead, can occur. The likelihood of cell death may be related to the stage of the generative

cycle (Chapter 2), in which the cell is found at the time of irradiation exposure. Tumor cells irradiated *in vitro*<sup>52</sup> or pluripotent, hematopoietic murine stem cells irradiated *in vivo*<sup>23</sup> are more affected by irradiation while in  $\text{G}_1$  or  $\text{G}_0$  than during DNA synthesis.

*Radiation protection*<sup>96</sup> may be achieved by physical shielding or by the use of an agent that either absorbs some of the energy of ionization, reacts with free radicals, or alters the biologic target so that it is less readily damaged. Among the most effective of such agents are the sulfhydryl-containing aminoethiols that are strong reducing agents at cellular temperature and pH. Reduced  $\text{O}_2$  will also protect cells. All these agents have the effect of reducing the radiation dose; they must, of course, be present at the time of exposure.

Certain treatments given to exposed mammals after irradiation can protect the animals from death by accelerating the replacement of damaged cells in critical tissues without changing the initial damage produced by x rays. For example, enhanced survival of mice receiving whole-body irradiation can be achieved by injecting a variety of substances, such as endotoxin, before irradiation or by bleeding the animals before or immediately after irradiation.<sup>19</sup> In these circumstances the cells are not protected individually from irradiation, but, rather, stem cell compartments are either expanded in size or stimulated to divide more rapidly. As a consequence, post-irradiation recovery of hematopoiesis is accelerated and death due to neutropenia or thrombocytopenia is avoided.

All cells are subject to damage by irradiation, but their sensitivity varies from organ to organ and from species to species. Single exposure of animals to whole-body irradiation (WBI) results in death at certain predictable doses. For example, mice given 5000 or more rads of WBI will die within a few hours of apparent x-ray damage to the brain cells. Given 1200 rads, they will die in three to six days from apparent x-ray damage to the gut and, given 900 rads, they will live for eight to fifteen days and die of infection or bleeding due to pancytopenia secondary to hemato-

poietic damage (page 1714). The dose of WBI resulting in hematopoietic death in man is probably 300 to 500 rads. The "gut death" and "cerebral death" doses of WBI in man have not been approximated with any accuracy. As an example of extreme species variability, one may cite the fact that the shark's brain is not damaged significantly until doses in excess of 30,000 rads are given.<sup>144</sup>

Insofar as has been determined with clarity, all effects of irradiation are the direct result of damage to the cells exposed to irradiation. *Abscopal effects*, effects of irradiation on organs that are not irradiated but are injured as the result of irradiation of a distant organ, have often been postulated, but have never been proved. Most studies dealing with possible abscopal effects consisted of investigation of effects on the hematopoietic system, such as general bone marrow depression following repeated irradiation to the spleen.<sup>21</sup> Since it is now known that the circulating and migratory pathways of hematopoietic stem cells include the spleen (Chapter 2), the results of such studies may be explained by irradiation of stem cells rather than being due to true abscopal effects.

### Toxic Effects of Radiotherapy

The toxic effects of radiotherapy can be divided into complications occurring during therapy, those occurring within a few months of completing therapy, and remote complications. The remote complications generally are limited to a higher incidence of AML and of certain other forms of malignancy in irradiated patients than in those not irradiated, and were discussed in Chapter 46.

The *hematopoietic system* (page 1714), the gastrointestinal tract, and the skin are most often affected during radiotherapy; the toxic effects in these tissues are usually reversible when therapy is stopped.

The epithelium of the entire *gastrointestinal tract* is a rapidly renewed cellular system and is quite sensitive to irradiation.<sup>96</sup> Thus, depending upon the area irradiated, symptoms and signs of gastrointestinal damage are common. The throat and oral cavity may

become inflamed and even ulcerated, producing pain and dysphagia. Esophagitis may occur. Irradiation of the stomach regularly induces anorexia and nausea, and vomiting often occurs. Irradiation of the small and large intestine may result in malabsorption and diarrhea and, in extreme cases, bloody diarrhea may occur, a serious and sometimes fatal complication. Residual evidence of damage to the gut following recovery from acute radiation toxicity is unusual.

The *skin* becomes erythematous and tender. Before the introduction of megavoltage equipment, severe inflammation of the skin progressing to desquamation and ulceration was the primary factor limiting the dose. Even with megavoltage rays, some erythema is common, as is permanent loss of body hair and hyperpigmentation of skin in irradiated areas. Telangiectatic lesions may be produced. Subcutaneous fat necrosis, followed by subcutaneous fibrosis, is rare after a single course of radiation therapy, but occurs in areas that have been treated on more than one occasion.<sup>96</sup>

More serious effects of irradiation that may not become apparent until a course of irradiation has been completed most often are due to damage to lung, pericardium, kidney, and liver.

**RADIATION PNEUMONITIS AND FIBROSIS OF LUNG.**<sup>96</sup> Clinically significant lung damage is rare when less than 1000 rads are given within a six-week period, but becomes increasingly more frequent and more severe as the dose is increased above that level. In a series of 248 patients with HD, treated by "mantle irradiation" (see Chapter 50) with a mediastinal dose of at least 4000 rads, 6.4% developed clear evidence of radiation pneumonitis despite careful shielding of lung tissue. However, only one patient died of this.<sup>96</sup> When the lungs themselves were treated for pulmonary HD or for prophylactic purposes with 1500 rads, one third of 69 patients developed pneumonitis; in eight this was severe and in four it was fatal.<sup>96</sup> In typical cases the patient shows no evidence of pulmonary disease for at least two months following completion of therapy and the interval may be

as long as a year. A dry, hacking cough usually is the first symptom. In those with severe cases, dyspnea and all the symptoms and signs of respiratory failure may develop. Chest x ray discloses diffuse, fine, or mottled densities in the affected areas and mediastinal shadows often appear broadened with quite irregular mediastinal-pulmonary borders. Histologic studies indicate an initial interstitial inflammatory reaction with prominent giant-cell infiltration that progresses to fibrosis.

In patients with mild cases, complete resolution of symptoms may take place within two to three months, although permanent "increased markings" may be seen in chest x rays. In other patients, permanent and even fatal degrees of pulmonary insufficiency may result.

No therapy is of proven benefit for radiation pneumonitis, although at least transient symptomatic improvement may result from steroid administration.<sup>98</sup> *Prevention*, by shielding the lung and perhaps by lengthening the time interval in which a total irradiation dose is delivered,<sup>99</sup> is the most effective step that can be taken.

**PERICARDITIS AND PERICARDIAL FIBROSIS.** These complications usually occur only in patients receiving at least 3500 rads to the heart. Clinically apparent pericarditis has been observed in approximately 5% of such patients.<sup>96</sup> From a few months to four years following irradiation, signs and symptoms of acute pericarditis may develop or the acute phase may not be evident, cardiac tamponade due to effusion or to pericardial fibrosis being the first indication of this complication. In other patients, no symptoms are evident, but an enlarging cardiac silhouette noted on chest x ray suggests the onset. In the majority of patients, spontaneous resolution of clinically evident disease occurs, but in some the severity of pericardial fibrosis requires decortication.

**RADIATION HEPATITIS.**<sup>97,99,188</sup> This complication may develop after doses of 2400 rads or more have been delivered to the entire liver. In one series of patients in whom 2450

to 2920 rads were delivered to the liver during the course of abdominal irradiation for ovarian carcinoma, 14 of 65 developed radiation hepatitis which was fatal in 11.<sup>188</sup> Hepatitis is evident within six months of irradiation in most patients, but symptomatic onset may be delayed for as long as three years.<sup>188</sup> Hepatomegaly and hepatic tenderness are common and ascites may develop, but jaundice usually does not occur. Results of liver function tests are quite variable, but serum alkaline phosphatase and bromsulfalein retention are increased in most subjects. The hepatocyte is quite radioresistant; radiation hepatitis appears to be the result of damage to supporting tissue rather than to injury of hepatocytes per se.<sup>99</sup> The incidence and severity of radiation hepatitis in rats is reduced when heparin is given for anticoagulation during radiation.<sup>99</sup> Complete recovery may occur in patients with mild cases or portal hypertension and/or hepatic failure of varying severity may be a permanent and often fatal sequel.

**RADIATION NEPHRITIS.**<sup>96,124</sup> When more than 2000 rads have been delivered to the kidney, radiation nephritis may ensue. Following a latent period of six to twelve months from onset of irradiation, edema, nausea, vomiting, headache, and other symptoms associated with azotemia appear. Urinalysis reveals proteinuria, granular and hyaline casts, and often a fixed specific gravity. The blood urea nitrogen is increased and hypertension may develop. Histologic renal changes include thickening of the capsule, hyaline obliteration of glomerular capillaries, and intertubular fibrosis with tubular atrophy. Progressive renal failure may lead to death. In some patients the condition may become stabilized with continuing, but nonprogressive, renal impairment, and a clinical course similar to that observed in chronic glomerulonephritis may ensue.

**OTHER TOXIC EFFECTS.**<sup>96</sup> The gonads are injured to some degree by almost any dose of irradiation.<sup>96</sup> Spermatogenesis and ovulation are inhibited, transiently by small doses, but permanently by large doses. Approxi-

mately 13% of patients whose *thyroid gland* has been irradiated in conjunction with "mantle" therapy for HD (Chapter 50) have developed hypothyroidism.<sup>96</sup> The growth of the *skeletal system* is affected in children. Transverse myelitis is a rare but serious complication of large-dose irradiation to the *spinal cord*. Other toxic effects of radiotherapy include osteitis, cystitis, and "pulseless disease" presumably due to arteritis.<sup>96</sup>

### The Alkylating Agents

The prototype of the alkylating agents, mechlorethamine (nitrogen mustard, HN2), was the first chemotherapeutic agent of proven benefit against human tumors. It was developed as a result of chemical warfare experimentation during World War II and its clinical usefulness was soon demonstrated.<sup>72,193</sup>

The spectrum of antitumor activity of subsequently synthesized alkylating agents such as chlorambucil, busulfan, cyclophosphamide, and melphalan is similar to that of HN2, but differs to the degree that each has found a useful place in antitumor therapy.<sup>168</sup> Although all of the four drugs just mentioned have the distinct advantage over HN2 of effectiveness when given orally, HN2 continues to have a place in current chemotherapy.

### Mechanism of Action

Alkylating agents, such as HN2, ionize within cells, forming highly reactive intermediate compounds (free radicals) that react with and damage a variety of normal cellular constituents.

The range of their effects upon cells is so broad as to negate exact definition of their primary effect.<sup>189</sup> The  $\beta$  chloroethyl groups of HN2 ionize to become positively charged ethyleniminium derivatives. A major mechanism of the cytotoxicity of HN2 is thought to be the combination of these derivatives with negatively charged guanine moieties of DNA. It seems likely that these drugs are transported into cells by masquerading as

normal compounds for which physiologic carrier systems exist. For example, there is evidence that HN2 gains access to cells via the normal choline transport system.<sup>70</sup>

The similarity of the clinical spectrum of activity of various alkylating agents to that of ionizing irradiation has led to the description of their effects as being *radiomimetic*. Yet, it is clear that the chemical changes induced in cells by alkylating agents differ significantly from those induced by irradiation.<sup>1</sup> A final common pathway of cellular damage may exist, but it is initiated differently by x ray and by various alkylating agents.<sup>1</sup>

The mechanism of resistance to HN2 and to other alkylating agents is unknown.

### Nitrogen Mustard<sup>122,123,153,197</sup>

Mechlorethamine (nitrogen mustard, HN2) has the chemical formula:

The usual dose is 0.4 mg/kg, given intravenously as a single dose, or 0.2 to 0.3 mg/kg given on each of two successive days. The dose may be repeated every four to six weeks, depending on the rate of recovery of the bone marrow. Once HN2 is solubilized for injection, rapid *in vitro* degradation of the drug begins. Consequently, it must not be placed in solution until the physician is ready to administer it. Since it is a severe vesicant, great care must be taken to avoid injection of any of the drug into cutaneous or subcutaneous tissues. An intravenous infusion of saline or glucose solution should be established through a relatively large-bore needle (18 gauge or larger) and HN2 should be injected through the tubing through which the saline or glucose infusion is flowing freely.

The toxicity of HN2 is dose related and consists of acute gastrointestinal upset and bone marrow depression as well as the previously described vesicant effect. Nausea and vomiting may begin within a few minutes of injection and, while vomiting usually subsides within six hours, nausea and anorexia may persist for a day or two. Both cycling

and  $G_0$  cells that are capable of proliferation are affected by HN2. The nadir of neutropenia and thrombocytopenia usually occurs within two weeks after a dose of HN2 and blood values are back to normal within four weeks in most patients.

**Chlorambucil (Leukeran,  
CB. 1348)**<sup>122,123,153,197</sup>

The chemical formula of chlorambucil is:

The usual dose is 0.1 to 0.2 mg/kg given orally daily. The reliable oral absorption of chlorambucil and its relatively prolonged plasma half-life as compared to that of HN2 are thought to be due to the substitution of electrophilic groups on the nitrogen atom.<sup>1</sup>

Toxicity is primarily hematologic and in that respect chlorambucil is quite similar to HN2. Nausea, vomiting, and anorexia are unusual. Pulmonary fibrosis, similar to that caused by busulfan, has been mentioned as a rare toxic effect and the possibility of hepatotoxicity has been raised.<sup>3,107</sup>

**Cyclophosphamide (Cytosan,  
CTX)**<sup>122,123,153,197</sup>

Cyclophosphamide's chemical formula is:

Oral or intravenous routes may be used for its administration. Since CTX is not locally irritating, in solution it may be directly and rapidly injected into a vein. The parent compound is not cytotoxic, but becomes so when converted to a variety of intermediates in the liver. When CTX is used in long-term oral therapy, 2 mg/kg, given once a day, is the usual tolerated dose. Larger doses may be given initially for short periods or large-dose intermittent therapy can be used. Thirty to 50 mg/kg can be administered as a single intravenous injection, repeated every three to

four weeks. This regimen may be superior to daily oral therapy in multiple myeloma (Chapter 52), but has not been tested extensively.

The toxicity of CTX is similar to that of HN2 in respect to the bone marrow, but there is suggestive evidence that megakaryocytes are affected less than erythrocyte and granulocyte precursors. Anorexia, nausea, vomiting, stomatitis, and diarrhea are unusual, but may occur. Severe hemorrhagic cystitis that may be fatal occurs and dehydration seems to contribute to the development of hemorrhagic cystitis. Alopecia is common, the nail beds may be affected, and the nails exhibit transverse ridging. Hyperpigmentation of the skin may occur.

**Busulfan (Myleran)**<sup>122,123,153,197</sup>

Busulfan has the following chemical formula:

It is given orally, 4 to 6 mg/day in adults, until a desired effect is achieved or toxicity supervenes. Although it is active against a variety of tumors, it is employed almost exclusively in CML (Chapter 48).

Hematologic toxicity, while similar to that caused by HN2, is often of longer duration than that of HN2. This may be explained by the marked and somewhat selective effect of busulfan on pluripotent hematopoietic stem cells observed in mice.<sup>23</sup> Hyperpigmentation of the skin is common and is dose related. Anorexia, nausea, and vomiting are unusual. A variety of rare, but severe and poorly understood, complications attend the use of busulfan. In general, these have been associated with continuous administration of small doses for months or years. "Busulfan lung"<sup>230,219,243,193a</sup> is associated with cough and progressive dyspnea with respiratory insufficiency eventually leading to death. Lung biopsy studies have suggested that the initiating factor is intra-alveolar exudation of fibrin with subsequent organization and fibrosis. A syndrome with features similar to those of Addison's disease has been reported in which adrenal function was normal.<sup>110</sup>

Addison's disease due to ACTH deficiency has also been reported.<sup>173</sup> Amenorrhea may occur. Other reported toxic effects of the long-term use of busulfan include posterior subcapsular cataracts,<sup>146</sup> erythema multiforme,<sup>50</sup> and porphyria cutanea tarda.<sup>109</sup>

**Melphalan (Phenylalanine Mustard, Alkeran, L-Sarcolysin)**<sup>122,123,153,197</sup>

The chemical formula of melphalan is:

Melphalan is given by mouth, either in a dose of 0.05 to 0.1 mg/kg/day as long-term therapy or as a large, intermittent dose of 0.25 mg/kg/day for four days every six weeks (Chapter 52). This L-phenylalanine derivative would be expected to be more active against protein synthetic processes than most other alkylating agents and this may explain its superiority in multiple myeloma.

Toxicity of melphalan seems limited to HN2-like marrow effects and moderately frequent, dose-related anorexia that may be associated with nausea and vomiting.

### Other Alkylating Agents

A variety of other alkylating agents have been synthesized, but have had no apparent advantage over the five widely used drugs that have just been discussed. Thio-TEPA was in widespread clinical use some years ago and was the first orally administered alkylating agent. Its dose-related hematologic toxicity seemed to be more erratic and unpredictable than that of subsequently synthesized alkylating agents and it is now used rarely in the treatment of patients with hematologic neoplasms. One possible current use for the drug may be in the local treatment of malignant effusions (see Chapter 54).

### Antimetabolites

Antimetabolites affect cells by interfering with specific enzymatic conversion of essential metabolites. All useful agents employed

thus far (folate antagonists, 6-MP and related drugs, cytosine arabinoside, and hydroxyurea) affect DNA synthesis and are cycle-active agents.

### Antifolic Acid Compounds

Antifolic acid compounds, first tested clinically in 1947, provided the first useful therapy for AL. Aminopterin was the first agent used, but has been supplanted by methotrexate.

**Methotrexate (Aminopterin, MTX)**<sup>14,87,122,123,153,197</sup>

The chemical formula of MTX is:

The drug can be given by mouth, intravenously, or subcutaneously and is also used for intrathecal therapy (see Chapter 54). A wide variety of dosage schedules have been employed. Some appreciation of the pharmacology of MTX is essential in understanding the rationale of the various regimens and their toxicity. Thus, the time that an effective plasma level is maintained is more important than is the peak plasma level achieved. The drug is filtered and excreted by the kidney in direct proportion to its concentration in plasma and it must be used with extreme caution, if at all, in patients with significant impairment of renal function. Its absorption after subcutaneous injection is faster than after oral administration and, consequently, the effective plasma level may be maintained for a shorter time after subcutaneous than after oral therapy. After intrathecal (i t) injection the drug is released very slowly to the blood. Thus, a single dose of 15 mg given i t may induce hematologic toxicity; 15 mg given orally or subcutaneously will have progressively less effect, while the same dose

given rapidly intravenously may have no detectable effect.

The mechanism of action of MTX<sup>14,87,89</sup> is through competitive inhibition of dihydrofolate reductase, the enzyme that catalyzes the conversion of folic acid to tetrahydrofolic acid (THF) and structurally related derivatives. In the presence of inadequate amounts of THF, DNA synthesis is inhibited and cells become megaloblastic, or, if severely depleted, may die.<sup>57</sup> For practical purposes, MTX therapy is analogous to the induction of a very severe deficiency of folic acid. Folic acid, as such, does not inhibit the effect of MTX, but the coenzyme, citrovorum factor, formed by the acceptance by THF of a single carbon fragment, does. Thus, administration of citrovorum factor at the time of or shortly after MTX administration reduces the effects of MTX. However, there is little evidence that citrovorum factor, given after MTX has been cleared from the blood, will reverse its toxicity.

Resistance to the effects of MTX develops because tumor cells can acquire the ability to synthesize abnormally large amounts of dihydrofolate reductase, thereby degrading MTX and rendering maximally tolerated doses for normal cells ineffective in killing tumor cells.<sup>14,87,89</sup> However, in closed spaces such as the CSF, a concentration of MTX sufficient to overcome the ability of the resistant cells to synthesize the reductase enzyme can be achieved (Chapter 54).

Hematologic toxicity is dose related, but is rapidly reversed by discontinuing use of the drug. Macrocytosis and megaloblastic changes in the marrow usually are not considered indications for interrupting therapy unless accompanied by progressive anemia. Growth of gastrointestinal epithelial cells is markedly affected by MTX with resulting mouth ulcers and diarrhea. Persistent therapy with MTX in patients with diarrhea may lead to hemorrhagic enteritis and perforation of the bowel. Thus, diarrhea and/or mouth ulcers are indications for interruption of therapy. Hepatic dysfunction, as evidenced by abnormal results in liver function tests, is fairly common during MTX therapy.<sup>42,62,92</sup> In a small percentage of patients

receiving long-term therapy, hepatic fibrosis with hepatomegaly and portal hypertension may develop and may prove fatal. Abnormal findings in liver function tests may not be indications for interrupting MTX therapy, but enlargement of the liver is. If therapy is stopped before hepatic fibrosis has become extensive, the fibrotic process usually does not progress further, but it is not reversed. We are familiar with one patient with ALL, currently in her fifteenth year of remission, who has had nonprogressive hepatomegaly with fibrosis and splenomegaly for 13 years after MTX therapy was discontinued. An acute, severe pulmonary syndrome characterized by fever, cough, dyspnea, cyanosis, and diffuse bilateral pulmonary infiltration, which resembled an allergic granulomatous reaction, has been observed during MTX therapy<sup>39</sup> and may prove fatal.<sup>149</sup> Alopecia is common, but dermatitis and nail changes are unusual. Osteoporosis, severe enough to produce pathologic fractures, has developed in children on long-term maintenance therapy with MTX.

Trophoblastic tissue is sensitive to MTX to such an extent that the drug is useful in the treatment of trophoblastic tumors as well as in inducing abortion.<sup>169</sup> MTX is exceedingly teratogenic in man if given in doses too small to induce abortion during the first trimester of pregnancy<sup>132</sup> (Chapter 54).

#### 6-Mercaptopurine (Purinethol, 6-MP)<sup>78, 79, 122, 123, 153, 197</sup>

The chemical formula of 6-mercaptopurine is:

A single, daily, oral dose of 2.5 mg/kg is the standard form of administration, but other forms such as intermittent large doses<sup>63</sup> have not been evaluated extensively. Other purine analogs such as 6-chloropurine,<sup>192</sup> thioguanine, and various derivatives of 6-MP such as 6-MP riboside<sup>50</sup> are similar to 6-MP in antitumor effects and in toxicity.

6-MP reacts with 5-phosphoribosyl-1-pyrophosphate, producing 6-MP ribonucleotide, the active antitumor compound. This reaction is catalyzed by a pyrophosphorylase and one mechanism of resistance to 6-MP may be the emergence of tumor cells containing little or no such enzyme, although this is not always the case.<sup>80</sup> The antitumor effect is exerted primarily by inhibiting purine synthesis and, consequently, DNA synthesis. This may be accomplished by inhibition of conversion of inosinic acid to adenylic and guanylic acid, suppressing *de novo* purine biosynthesis, perhaps by feedback inhibition related to the formation of ribosylamine 5-phosphate from glutamine and 5-phosphoribosyl-1-pyrophosphate, as well as through other effects on purine synthesis. In the belief that the effects of 6-MP are enhanced by allopurinol when the latter is used to prevent hyperuricemia (Chapter 54), it has been the practice to reduce the dosage of 6-MP in such circumstances. However, this recommendation has been challenged.<sup>175a</sup>

Hematologic toxicity of 6-MP is reversed rapidly when use of the drug is discontinued. Anorexia, nausea, and vomiting are fairly common and are dose related, but stomatitis, diarrhea, and severe gastrointestinal toxicity are rare. Jaundice, seemingly on an idiosyncratic rather than on a dose-related basis, is fairly frequent.<sup>38,55</sup> The jaundice is cholestatic in type with bile stasis and some degree of necrosis evident on liver biopsy. The onset of such jaundice generally is considered a contraindication to further 6-MP therapy, but reports of disappearance of jaundice despite continuation of 6-MP therapy have been published.<sup>22</sup> Whether the jaundice was, in fact, due to 6-MP cannot be determined with certainty. Fever has been reported as a complication of 6-MP therapy.<sup>154</sup> As with any drug that has some selective effect on DNA synthesis, megaloblastosis may be induced.

**Cytosine Arabinoside**  
(1-β-D-Arabinofuranosyl  
Cytosine, Cytosar, Ara-C)<sup>120</sup>

Ara-C has the following chemical formula:

This synthetic, cycle-dependent nucleoside is given intravenously or subcutaneously, as well as intrathecally (Chapter 54). Effective doses are quite similar irrespective of the route of administration.<sup>64</sup> There is no established optimal dosage schedule (see Chapter 47). Ara-C is converted to active phosphorylated derivatives intracellularly and these directly and specifically inhibit DNA synthesis. The exact mechanism of action has not been determined, but the action reflects inhibition of DNA polymerase, at least in part.

Hematologic toxicity is dose related and recovery is prompt after therapy with the drug has been stopped. Megakaryocytes seem exceptionally sensitive to Ara-C and severe thrombocytopenia is often induced. A rebound thrombocytosis may follow cessation of therapy. Anorexia, nausea, and vomiting are common. The mechanism of production of gastric toxicity is unclear, but symptoms may appear within a few minutes after a dose of Ara-C has been given and vomiting rarely persists for more than four to six hours. Diarrhea and oral ulceration are unusual, but may occur. Hepatitis has been reported.

**Hydroxyurea (HU)<sup>34</sup>**

Hydroxyurea's chemical formula is:

This compound has been known for many years, but its antitumor activity was not recognized until the late 1960's. Although optimal dosage schedules have not been developed, HU may be given as an oral dose of 80 mg/kg, daily for three days and that dose may be repeated at six-week intervals, provided toxicity has subsided.

Hydroxyurea inhibits DNA synthesis by

inhibiting ribonucleoside diphosphate reductase and perhaps by other mechanisms as well.

In addition to hematopoietic toxicity, nausea, vomiting, and diarrhea are common, but are usually mild and stomatitis is unusual. Alopecia may occur and rashes, possibly of idiosyncratic nature, have been reported.

### Stathmokinetic Agents

Stathmokinetic agents selectively affect cellular microtubules<sup>126</sup> and thus interrupt formation of mitotic spindles, producing arrest of mitosis in metaphase. Death of the cell usually follows. Thus, these are highly specific, cycle-active antimitotics. However, other effects such as inhibition of DNA-dependent RNA polymerase may also occur.<sup>126</sup>

#### *Vinblastine (Velban, VLB)*

Vinblastine, an alkyloid derived from the periwinkle plant, is given intravenously, initially in a single dose of 0.1 to 0.15 mg/kg. This dose is repeated every seven to ten days and is increased slowly to as much as 0.3 mg/kg if not prevented by severe toxicity.

Hematologic toxicity is transient and dose dependent. Nausea, vomiting, and anorexia are fairly common, as is stomatitis. Either diarrhea or constipation may occur. Neurologic complications like those associated with vincristine are uncommon, but may occur, as may alopecia.<sup>27</sup>

#### *Vincristine (Oncovin, VCR)<sup>49</sup>*

Vincristine is extracted from the same plant as VLB and is very closely related in chemical structure, but there are significant differences in the spectra of antitumor activity (see Table 55-2) and type of toxicity of the two drugs.

VCR is given intravenously in a once weekly dose of 1.0 to 1.5 mg/m<sup>2</sup>. The total dose/week should not exceed 2 mg. Differences in the mechanism of action of VCR and VLB have not been elucidated.

Toxicity is primarily neurologic (Table 55-5).<sup>150</sup> Loss of deep tendon reflexes in the legs and mild paresthesias, usually involving the feet and hands, may occur after the first dose and are present in most patients by the third dose. Many physicians do not consider loss of reflexes in the legs and mild paresthesias as contraindications to further therapy, and in one series of 100 patients no serious toxicity was noted with a total cumulative dose of less than 7 mg.<sup>49</sup> However, patients may develop severe paraparesis when another dose is given in the face of minimal neurologic toxicity and, unless there are compelling reasons to give additional VCR, it usually is better not to. Likewise, severe complications, such as bladder atony<sup>73</sup> have followed minimal doses without other premonitory neurologic changes. Certainly the onset of severe paresthesias, any motor weakness in the extremities, hoarseness, ptosis, double vision, or severe constipation should be indications for stopping VCR therapy. Improvement occurs in neurologic lesions when therapy is stopped, but recovery may require months and permanent damage may remain if toxicity is severe. Alopecia is common, but hematologic toxicity is unusual. Only in an occasional patient is severe bone marrow aplasia produced.<sup>150</sup>

### Other Stathmokinetic Agents

*Colchicine* has a stathmokinetic effect, but only in vivo at dosages precluded by nausea and vomiting. A colchicine-like agent, *demicolcine*, was shown to be effective in CML,<sup>117</sup> but since it offers no advantage over busulfan, it is no longer available.

### Antibiotics

Antibiotics are antitumor compounds derived from living organisms.

#### *Daunomycin (Daunorubicin, DNR)*

Daunomycin was isolated from *Streptomyces peucetius*.<sup>77</sup> Optimal dosage schedules are not available, but this antibiotic is usually

**Table 55-5. Comparison of Drug-Related Neurologic Manifestations in Leukemic Patients Receiving Chemotherapy with and without Vincristine\***

<i>Clinical Manifestations</i>	<i>Combination Chemotherapy Including Vincristine (50 Patients)</i>	<i>Combination Chemotherapy without Vincristine (20 Patients)</i>
	<i>Number of Cases</i>	<i>Number of Cases</i>
Depression or loss of Achilles tendon reflex	50	0
Depression or loss of other deep tendon reflexes	24	0
Motor weakness (associated with neurologic dysfunction)	17	0
Slapping broad-based gait	11	0
Flaccid paralysis, lower extremities	2	0
Muscle pain and tenderness	4	3
Muscle atrophy	5	3
Paresthesias		
(combination chemotherapy only)	19	0
(chemotherapy and anti-biotics)	4	2
Discrete sensory deficits	0	0
Diplopia,		
other visual disturbances	6	3
Ophthalmoplegia (VI)	3	0
Ptosis (III)	5	0
Facial palsy (VII)	2	1
Paroxysmal jaw pain (V)	2	0
Mild abdominal pain	23	4
Moderate to severe abdominal pain, ileus	6	1
Difficulty in initiating micturition	2	0

\*From Sandler et al.<sup>150</sup> courtesy of the authors and Neurology

employed in brief "bursts" such as 2 mg/kg/day, given intravenously for three days.

A cytoplasmic enzyme, daunorubicin reductase, converts daunomycin to an active compound, daunorubinol, in the presence of NADH.<sup>90</sup> There is evidence to suggest that the myeloblasts of patients with AML who respond favorably to DNR contain high levels of this enzyme.<sup>76,90</sup> Synthesis of RNA and DNA is inhibited and there is specific interference with the G<sub>2</sub> phase of the cell cycle as well.<sup>167</sup>

Toxicity of DNR is severe. Marrow apla-

sia, seemingly of irreversible nature, may be produced, suggesting that DNR may not be a cycle-active agent exclusively. Cardiac toxicity, a severe cardiomyopathy which may be fatal, is partially dose related. It is uncommon in children unless a cumulative total dose of 900 mg/m<sup>2</sup> has been given, but has occurred in older patients with smaller doses.<sup>167</sup> Thus, there may be some hazard of cardiac toxicity with any biologically active dose of the drug. Other side effects include nausea, vomiting, and diarrhea; alopecia is common.

Drugs similar to daunomycin, such as the hydroxy derivative of daunomycin, *adria-*

mycin,<sup>34</sup> or a semi-synthetic methylated derivative,<sup>13</sup> are also active antitumor antibiotics. Whether their antitumor effect and their therapeutic/toxic ratio will lead to their replacing DNR in clinical use remains to be determined.

### *Bleomycin*<sup>17a,194,197</sup>

Bleomycin is the generic name for a group of related sulfur-containing glycopeptide antibiotics derived from *Streptomyces verticillatus*.<sup>174</sup> It is given intravenously, but optimal dosage schedules have not been defined; tolerable dose levels lie between 4 and 15 mg/m<sup>2</sup> administered twice weekly for a total of 12 doses.<sup>142</sup> According to one regimen, 15 mg are given daily for six days and then once weekly. Effects seem largely limited to lymphoid tumors and tumors of the skin.

The mechanism of action has not been elucidated completely, but cells are arrested in G<sub>2</sub>. At higher doses, DNA synthesis is inhibited while RNA and protein syntheses are little affected, and there is evidence for scission in single-stranded DNA.<sup>194,197</sup>

Bleomycin has no evident hematologic toxicity.<sup>23a</sup> If total doses in excess of 100 mg/m<sup>2</sup> are given, serious pulmonary fibrosis may become evident and commonly progresses to fatal pulmonary insufficiency.<sup>15</sup> The skin and skin appendages, such as nail beds, are affected and become inflamed and sclerotic, and alopecia is frequent. Nausea and vomiting may occur immediately after the drug is given and fever and chills are common. On occasion, anaphylactic shock and disseminated intravascular coagulation have been observed.

### *Other Antibiotics*

*Actinomycin D* and *mithramycin* are antibiotics that complex with DNA and inhibit DNA-directed RNA synthesis. They rarely have been used and have not been fully evaluated in the treatment of hematologic malignancies, in part at least because of their severe and varied toxic effects. The use of low doses of mithramycin in the control of hypercalcemia has been discussed (Chapter 52).

### Adrenal Glucocorticosteroids ("Steroids")<sup>37</sup>

The natural or synthetic steroids such as hydrocortisone, prednisone, prednisolone, or dexamethasone and ACTH all have the same spectrum of antitumor activity insofar as has been determined (see Table 47-5, page 1490, for comparison of ACTH, hydrocortisone, and prednisone in ALL). These agents are useful in the management of certain lymphoid neoplasms (Table 55-2).

The specific mechanism of the lympholytic effect of steroids is unknown.<sup>37</sup> Nonproliferating cells as well as those in cycle are affected and protein synthesis and mitosis are inhibited.<sup>56,100,139,180</sup> Lymphoid cells may have specific membrane-binding sites which may be used by steroids, such binding leading to cell death.<sup>10,118a</sup> Low levels of transcortin may enhance the lympholytic effect of steroids.<sup>182</sup> In patients with ALL who were no longer sensitive to steroids, binding sites were not demonstrable in lymphoblasts.<sup>10,118a</sup>

The optimum dosage of steroids has been fairly well delineated in ALL (Chapter 47). Higher doses are no better than a dose of 60 mg of prednisone per day in adults. There is no evidence that very large doses are advantageous in any of the other hematologic neoplasms. Thus, 1 mg/kg/day of prednisone given orally, or equivalent doses of other steroids, seems reasonable as initial therapy in adults, as does 2 mg/kg in children. However, although the lympholytic effect of steroids is rapid, it is transient. Alternate-day therapy, which reduces toxic effects, is not particularly effective in lymphoid neoplasms.<sup>125</sup> Maximum effect is achieved in four to six weeks in ALL (Chapter 47), CLL (Chapter 49), HD (Chapter 50), and NHL (Chapter 51). If the therapy is stopped within six weeks, repeated responses at later phases of disease may be obtained. Maintenance therapy with any dosage of steroids is clearly contraindicated in patients with ALL (Chapter 47) and is of no proven benefit as antitumor therapy in patients with any of the other hematologic malignancies.

The toxic effects of pharmacologic doses of steroids are so well known, so frequent,

and so varied that a comprehensive discussion is unnecessary here. They are listed in Table 13-6 (page 555). The use of steroids in short bursts of therapy, the best means of utilizing their lympholytic effect, does not produce many of the long-term ill effects associated with long-continued therapy, such as severe osteoporosis. However, infection, peptic ulceration, and diabetes are encountered with some frequency.

Infections with bacteria, fungi, and certain viruses, such as the herpes viruses, are more severe, if not more frequent, in patients receiving steroids<sup>116</sup> than in patients not given steroids. The reasons for this are not entirely clear. Steroids stabilize lysosomes and thus may inhibit killing of phagocytized organisms. Reduced reticuloendothelial clearance of injected particles has been reported in animals given steroids. Hydrocortisone and prednisone reduce the migration of phagocytes into inflammatory exudates, an effect that seems to provide a satisfactory explanation for the occurrence of severe infections during such therapy.<sup>17</sup> However, it has been reported that dexamethasone does not have such an effect and, in fact, increases the number of phagocytes entering an induced exudate in man.<sup>158</sup> Antibiotics used in prophylaxis against infection in steroid-treated patients have been ineffective, if not harmful.<sup>116</sup>

Other toxic effects encountered occasionally include panniculitis,<sup>94</sup> myopathy,<sup>115</sup> avascular necrosis of the femoral head,<sup>82</sup> and fatty infiltration of the liver and kidney.<sup>159</sup>

### Miscellaneous Agents

#### *L*-Asparaginase<sup>32,140</sup>

Inhibition of growth of murine neoplasms by guinea pig serum<sup>97</sup> was found to be the result of the presence of an enzyme, *L*-asparaginase,<sup>28</sup> and clinical trials of this enzyme, harvested from *E. coli*, were initiated. Certain human tumor cells apparently require exogenous asparagine for growth, although asparagine is generally considered a nonessential amino acid. *L*-Asparaginase

reduces blood asparagine to undetectable levels, thereby depriving the tumor cell of this amino acid.

*In vitro* susceptibility of leukemic cells to *L*-asparaginase unfortunately is not particularly useful in predicting *in vivo* effect.<sup>86,175</sup> This may be due to the ability of certain tumor cells to enhance asparagine synthesis by increasing their level of asparagine synthetase activity in response to exogenous asparagine depletion.<sup>86</sup>

*L*-Asparaginase is given intravenously, but the optimal dose has not been defined. In initial trials in patients with ALL, very large doses, in excess of the dose needed to depress blood asparagine to unmeasurable levels, were used.<sup>32</sup> Doses as small as 1000 international units (iu) once or twice per week may be as effective as larger doses.<sup>84a,140</sup>

The true toxicity of *L*-asparaginase is difficult to define since this enzyme is not chemically pure. Many of the reported side effects may be due to contaminants, such as foreign protein and bacterial endotoxin. Certainly the occasional occurrence of anaphylactic shock suggests that *L*-asparaginase contains strong, foreign antigens. Reported side effects include severe hepatitis and pancreatitis; anorexia, nausea, vomiting, and diarrhea; fever; weight loss, lethargy, somnolence, and confusion; disseminated intravascular coagulation; hypo- and hyperlipidemia; hypocalcemia and azotemia. No effects are noted on normal bone marrow cells in most patients. However, in an occasional patient, complete aplasia is produced.<sup>113</sup> We have seen two such patients and in both rapid marrow recovery occurred.

Toxicity may be reduced by giving relatively small doses (1000 iu/wk rather than 10,000 iu/wk), but even quite small doses have been associated with very severe toxicity.<sup>140</sup> Of 105 children with ALL<sup>113</sup> who were given 200 iu/kg/day, 45 developed serious toxicity: anaphylaxis occurred in seven, pancreatitis in four (all died), hyperglycemia in four (one died), hepatotoxicity in 14 (two died), marrow aplasia in two (one died), atopic rash in four, CNS signs in nine, and hypertension in one, with a total fatality rate of almost 8%.

*Procarbazine (Natulan<sup>®</sup>, PC)<sup>33,34</sup>*

Procarbazine has the chemical formula:

This methylhydrazine derivative is given in an oral dose of 50 to 150 mg/m<sup>2</sup>/day with appropriate adjustment of dose when toxicity occurs.

PC may act in part as an alkylating agent, but additional mechanisms of action exist, as suggested by the fact that cross resistance with other alkylating agents is not evident clinically. It inhibits synthesis of DNA and RNA as well as protein, but the mechanism of action is not completely understood.<sup>33</sup>

Toxic effects, in addition to marrow depression, include anorexia and, less commonly, nausea and vomiting. Central nervous system depression and peripheral neuropathy may occur, particularly in the elderly, but are largely avoided if daily doses do not exceed 300 mg. The drug is an effective monamine oxidase inhibitor, an action that must be kept in mind when prescribing other drugs during procarbazine therapy.

*Nitrosoureas<sup>199</sup>*

Nitrosoureas are a relatively new class of compounds of which 1,3 bis (2-chloroethyl)-1-nitrosourea (BCNU) is the parent compound.<sup>34,198</sup> BCNU is given intravenously in single doses ranging from 100 to 250 mg/m<sup>2</sup>.<sup>198</sup> It is dissolved in absolute methanol, diluted in saline solution, and infused in 10 to 30 minutes. Because of delayed and unpredictable hematologic toxicity the dose should not be repeated for four to six weeks.

Purine incorporation into both DNA and RNA is inhibited by BCNU, perhaps because of inhibition of de novo purine synthesis. Similar effects are observed with alkylating agents (page 1721). However, since BCNU has been of benefit in patients with HD who were resistant to the antitumor effects of alkylating agents, the mechanisms of action of BCNU and alkylating agents probably differ. It does

seem clear that BCNU affects noncycling as well as cycling cells.

Hematologic toxicity is the most serious side effect. This is often delayed and of unpredictable degree. The nadir of neutrophil and platelet depression is not reached in the average patient until 30 days after a single dose has been given.<sup>198</sup> Fatal aplasia is a hazard any time the drug is used.

Within two hours following injection, flushing of the skin and conjunctivae is often noted, effects which clear rapidly. Nausea and vomiting may occur acutely and esophagitis, anorexia, dysphagia, and diarrhea have been noted occasionally. BCNU is a mild vesicant if infused into subcutaneous tissue. Severe hepatic and renal toxicity is induced in animals, but, except for mild, transient abnormalities denoted by liver function tests and elevation of blood urea nitrogen, hepatic and renal toxicities have not been noted in man.

Nitrosoureas closely related to BCNU, such as CCNU and methyl CCNU, are more lipid soluble than BCNU and have two pharmacologic advantages as compared to the parent compound. Their lipid solubility allows them to be used as oral rather than intravenous agents and they cross the blood-brain barrier more readily than does BCNU. Their activity against hematologic neoplasms and the toxicity of these agents, as compared to BCNU, remain to be determined.

*Other Agents*

*Dibromomanitol* is effective in CML patients at a dose of 250 mg/day administered orally, but a comparison with busulfan is not yet available nor has this drug received extensive trials in patients with other hematologic tumors. *Methy-GAG* (methylglyoxal-bis-guanylhydrazone) is active in AML, but its hematologic, gastrointestinal and cutaneous toxicity are so severe that trials have been limited. *Mitomycin-C* has proven antitumor effects in HD, NHL, and CML, but the antitumor dose and the dose causing bone marrow toxicity are so close that this agent is rarely used. The same objection limits the

use of *streptonigrin*, an agent with significant effects in NHL and HD. *Rifamycin* antibiotics, while of no proven benefit in human tumors, are interesting in that they constitute a new class of agents that inhibit RNA-dependent DNA polymerase (Chapter 46). Certain derivatives of the parent compound, rifampicin, have significant inhibitory effects on viral RNA-dependent DNA polymerase and have a greater effect on the DNA polymerase of leukemic cells than on that derived from normal cells.<sup>165,195</sup> The synthetic, double-stranded RNA, *poly 1:C*, induces production of interferon, is a moderately effective antiviral agent, and has proven effects against certain virus-induced murine neoplastic diseases.<sup>197</sup> It represents a new class of agent, not yet tested in human neoplasms. Other agents of possible value, but as yet not fully tested in human tumors, include *streptozotocin*, an antibiotic that is chemically related to the nitrosoureas; *N-demethylepipodophyllotoxin thenylidene gluconide*, a stathmokinetic agent; and *5-azacytidine*<sup>96a</sup> and *guanazole*, drugs related to cytosine arabinoside.<sup>29</sup>

## Experimental Forms of Therapy

A variety of forms of therapy other than those discussed above have been or are being tested in the hematologic neoplasms, particularly in acute leukemia.

### Bone Marrow Transplantation

Successful transplantation of human bone marrow is possible between identical twins and also between non-twin siblings in whom the four major histocompatibility loci (HLA loci) (Chapter 12) are identical.<sup>44,59</sup> However, only between genetically identical siblings (twins) can transplantation be done with some degree of impunity. Identity of the HLA loci, while crucial to successful transplantation, does not insure tissue compatibility, which obviously depends on other loci as well.

The recipient is treated with potentially lethal doses of whole-body irradiation or cyclo-

phosphamide prior to transplantation.<sup>152,172</sup> This provides immunosuppression and also markedly reduces the total mass of leukemic cells. Large volumes of normal marrow are aspirated, filtered to remove clumps, and injected intravenously. If graft-versus-host disease develops,<sup>43,74,108,164a</sup> treatment is given with steroids and MTX, but this may be of no avail and the patient may die with severe liver and skin damage. A period of profound pancytopenia always follows engraftment before the new marrow grows to a functional size.

Complete remissions of acute leukemia have followed such engraftment, but most have been of short duration with leukemia recurring quickly.<sup>43,75</sup> As discussed in Chapter 46, leukemia has occurred in the engrafted marrow in at least two instances. In terms of clinically useful therapy, marrow transplantation may have a greater role in treating patients with aplastic anemia or immune deficiency than those with leukemia.<sup>170</sup>

*Autologous marrow* can be obtained before therapy, stored, and reinfused, in the hope of permitting administration of larger doses of chemotherapy or irradiation to patients with diseases such as HD, but the benefit of this procedure is questionable.<sup>106</sup>

*Extracorporeal irradiation* of the blood has had some salutary effects in the chronic leukemias, but has not induced remissions in acute leukemia.<sup>4,36</sup> The spleen has been irradiated selectively in patients with lymphoma by passing a catheter into the splenic artery via the aorta and injecting ceramic or plastic microspheres in which <sup>90</sup>yttrium has been incorporated.<sup>8</sup>

### Immunotherapy

The possibility of modifying the growth of human neoplasms by administering specific antibodies or by causing the patient to mount an immune reaction against his own tumor has been an attractive hypothesis, intermittently pursued at the clinical level since the turn of the century.<sup>60,135</sup> The recent and rapid growth of our knowledge concerning immunity in general (Chapter 7) and of

tumor immunity in particular<sup>60,127,166</sup> has provided a sound base for undertaking clinical trials of immunotherapy. However, proof that useful immunotherapy of hematologic malignancies can be accomplished in man is lacking as yet, although it has been shown to be useful in a number of animal models.<sup>60,130,147</sup>

A number of observations suggest that immunotherapy may be feasible. First, there is evidence that most human tumors,<sup>136</sup> including leukemias,<sup>18,134,178</sup> possess a unique cell surface antigen not found on normal cells (Chapter 46). Thus, there is reason to believe that an immune response that would be specific for the tumor and fail to affect normal cells could be mounted. Second, the occurrence of spontaneous remissions in hematologic as well as in other types of malignant disease suggests that the host can somehow gain control of his own malignant condition. While this control could be due to factors other than immune mechanisms, there is excellent evidence that spontaneous resolution of murine neoplasms has an immune basis.<sup>60</sup> Third, there is evidence that an immune response to tumor is mounted by the human host.<sup>5,160</sup> The histologic appearance of the cellular response surrounding tumors or in lymph nodes draining tumors often resembles that noted with delayed hypersensitivity reactions or graft rejections. In vitro lymphocyte-induced tumor cytotoxicity has been demonstrated in some instances. For example, the lymphocytes from patients with ALL in remission are stimulated by exposure to autologous leukemic cells.<sup>66,118,144</sup> Circulating specific antibodies to the host's tumor are often demonstrable, as is blocking factor. Blocking factor, so named because it interferes with cytotoxic antibodies in vitro, probably consists of antigen-antibody complexes. Fourth, there is evidence that tumors may develop more frequently or spread more rapidly in the presence of immune deficiency. As discussed in Chapter 46, lymphomas have developed with greater than expected frequency in patients with congenital or iatrogenic immune deficiency. The prognosis of patients with tumors is poor if cell-mediated

immunity is impaired as compared to the course of those in whom it is intact.<sup>134,166</sup>

Thus, a basis for attempting immunotherapy of human tumors has been developed and in general it would appear that cell-mediated immunity is important in the control of tumors, while humoral immunity could be harmful as well as helpful.<sup>147</sup> The possible harmful nature of humoral immunity stems from the aforementioned blocking factor.<sup>85</sup> The presence of blocking factor may reflect excessive soluble tumor antigen compared to the amount of specific tumor antibody that is present and, indeed, its presence has been correlated with glomerular lesions similar to those seen in experimentally induced "antigen excess" nephritis.<sup>166</sup> Blocking factor reversibly inhibits the in vitro antitumor cytotoxic effect of sensitized lymphocytes. There is also a "deblocking" factor that may simply represent excess antibody, unbound to tumor antigen.<sup>127,134</sup> There is suggestive evidence that blocking factor may play an adverse role in vivo.<sup>83,134,166</sup> It often is demonstrable in the presence of active disease, but disappears after successful excision of tumor.

The methods being tested as approaches to immunotherapy can be divided into three categories: (1) active immunotherapy, (2) passive immunotherapy, and (3) nonspecific immunotherapy.<sup>134</sup>

*Active immunotherapy* consists of attempting to alter tumor antigens so that their antigenicity is enhanced. The most efficient active immunotherapy in animals may consist of intradermal injection of living, autologous tumor cells in insufficient number to produce a tumor.<sup>30,134</sup> This approach has not been utilized in man for fear that viable tumor cells would grow. Instead, cells rendered nonviable by irradiation, mitomycin C, freezing and thawing, or heating have been employed and highly antigenic carrier proteins have been added in an attempt to increase antigenicity in human experiments.<sup>134</sup> Isolation of pure preparations of human tumor antigens for injection has not yet been accomplished.

*Passive immunotherapy* consists of administering antitumor sera or lymphocytes. Antitumor sera, produced in animals against

human tumors, have been of little, if any, benefit.<sup>134</sup> However, as blocking factor, de-blocking factor, and humoral cytotoxic antibody relationships are clarified, antiserum therapy should probably be reevaluated. Lymphocytes from HLA-matched siblings or autologous lymphocytes grown in culture<sup>28,65,134</sup> or stimulated *in vitro* with PHA<sup>12,134</sup> have been infused with some suggestion of clinical benefit.<sup>134</sup> Transplantation of the spleen from a normal person to his identical twin who had lymphocytic leukemia was accomplished, but without appreciable benefit.<sup>135</sup> Studies of patients cross sensitized by injecting each others' tumors and then exchanging lymphocytes<sup>31,133,134</sup> are somewhat difficult to interpret since the sensitized lymphocytes would not survive the HLA barrier for an appreciable length of time. No evident effect was observed in patients with acute leukemia who were infused with lymphocytes from volunteer donors who had been injected with the patients' leukemic cells.<sup>6</sup>

Transfer factor,<sup>114</sup> the factor derived from lymphocytes which is capable of passing information of specific immune response from sensitized to nonsensitized patients (Chapter 7), is being investigated as a possible method of increasing the tumor-bearing host's immunity, as is immune RNA that can be extracted from sensitized, xenogeneic lymphocytes.<sup>47</sup>

*Nonspecific immunotherapy* is based on the thesis that if the host's immune system is stimulated by a nonspecific antigen, immune response to other antigens will be enhanced. Probably it was first used as antitumor therapy by Coley,<sup>138</sup> who observed regression of a tumor after erysipelas; this led him to develop a series of bacterial toxins whose injection led to tumor regression in some patients. Since it is now thought that the cellular immune system is primarily responsible for tumor immunity, rather than the humoral system, which was probably stimulated by Coley's toxins, agents that stimulate the cellular system, such as BCG, are under investigation. When BCG is injected into patients with leukemia or other tumors a

measurable increase in the host's antitumor immune response can be induced.<sup>134</sup> Proof of clinical benefit in such trials is lacking in leukemia patients (Chapter 47), but there is probable benefit in those with other tumors, such as melanoma.<sup>134</sup> "Adoptive" immunotherapy<sup>127</sup> is similar to passive immunotherapy in that lymphocytes from nonimmunized, but allogenic donors are given to patients; some moderate clinical benefit has been reported in patients with ALL<sup>156,178</sup> and in patients with other tumors.<sup>196</sup>

Since, in most animal models, immunotherapy is effective as preventive therapy or in reducing a very small volume of transplanted tumor, many current trials in man are directed toward attempting to prolong drug-induced remissions rather than with the object of reducing demonstrable tumor.<sup>128</sup>

### Other Forms of Therapy

*Exchange transfusion* led to transient remission in some patients with acute leukemia.<sup>15,16,130</sup> A controlled study that compared transfused fresh versus stored blood revealed that fresh, but not stored, blood reduced the blood leukocyte count in patients with leukemia.<sup>185</sup> Limited trials of fresh plasma infusions were of no apparent benefit in acute leukemia,<sup>35,45,79</sup> but no systematic investigation of the factor in fresh, normal blood, which influences leukemia, has been carried out.

Early attempts to treat leukemia as if it were a *deficiency disease* by giving liver, gastric mucosa, pancreas, small intestine, bone marrow, and embryonic rabbits or extracts thereof, were unsuccessful.<sup>35</sup> Thymectomy<sup>16,95</sup> and adrenalectomy<sup>183</sup> have been without apparent effect in ALL and AML, respectively. Transient repeated improvement was reported in a patient with AML given Sendai, Newcastle, and influenza virus,<sup>190</sup> and injection of Langat and Kyasanur forest disease virus led to improvement in a few patients with leukemia and in patients with a variety of cancers.<sup>179</sup> Induction of amino acid imbalance was of no apparent benefit.<sup>2</sup>

## Development of New Agents

The empiric program to develop and screen new anticancer drugs which is sponsored by the Drug Research and Development section of the National Cancer Institute is a primary source for the new drugs that reach the stage of clinical trials.<sup>69</sup> In this program, all agents are tested for effects upon growth of L-1210 leukemia, transplanted into mice. Crude natural products are also routinely tested for their effect on P-388 mouse leukemia. The magnitude of this program is illustrated by the fact that more than 49,000 crude natural plant extracts were tested through 1971. Materials that show activity in the primary screen also are tested for effects on B-16 mouse melanoma, mouse Lewis lung carcinoma, rat Walker carcinoma 256, and in an *in vitro* KB cell culture system. Those that show promise in the primary screens are then evaluated further in the following stepwise fashion: toxicity studies in dog and monkey, clinical trials to determine tolerated doses in man (phase I clinical trials), estimation of therapeutic activity in human cancer (phase II), and, finally, definitive trials designed to eradicate potentially sensitive human tumors (phase III).

In general it can be stated that most agents that have reached clinical trials have given evidence of antitumor activity in man, although the majority have not found widespread clinical use, either because of prohibitive toxicity or because they offered no apparent advantage over existing agents. Animal studies generally have been of value in predicting qualitative toxicity of various agents for man, but some unpredicted toxicity for specific organs has been encountered.<sup>88</sup> Tolerated dose levels in mice, rats, and dogs, in general, have been found to be similar to those in man when calculated on the basis of surface area rather than weight.<sup>88</sup>

# Part VI

## Pancytopenias and Myelophthasic Conditions

## *Pancytopenia, Aplastic Anemia, and "Pure Red Cell" Aplasia*

Pancytopenia  
Aplastic Anemia  
Acquired Aplastic Anemia  
Constitutional Aplastic Anemia  
Fanconi's Syndrome (Congenital Pancytopenia)  
Aplastic Anemia with Pancreatic Insufficiency  
Pure Red Cell Aplasia  
Acquired Acute Erythropoietic Hypoplasia  
Chronic Acquired Erythropoietic Hypoplasia  
Constitutional Erythroid Hypoplasia

### **Pancytopenia**

#### **Definition**

*Pancytopenia* refers to a reduction in all three formed elements of the blood—the erythrocytes, leukocytes, and platelets. It is not a disease entity; rather it is a triad of findings that may result from a number of disease processes (Table 56-1).

#### **Pathophysiology**

The mechanism by which pancytopenia develops has not been studied extensively. In some of the conditions listed in Table 56-1 there is a marked decrease in hematopoietic cell production in the bone marrow either as

a result of destruction of marrow tissue by toxins (acellular or hypoplastic marrow) or perhaps because of replacement by abnormal or malignant tissue. In such patients, bone marrow biopsy usually provides the diagnosis. In other patients, however, the marrow may be normally cellular or even hypercellular<sup>7,35,44,48,53</sup> and no abnormal cells may be present. The mechanisms leading to pancytopenia in such patients are thought to include: (1) ineffective hematopoiesis with cell death in the marrow; (2) formation of defective cells that are rapidly removed from the circulation; (3) sequestration and/or destruction of cells as a result of antibodies; and (4) trapping of normal cells in a hypertrophied and overactive reticuloendothelial system. Ferrokinetic and red cell kinetic studies have demonstrated active but ineffective erythropoiesis in some patients,<sup>16</sup> and it seems likely that the same mechanisms apply to granulocytes<sup>4</sup> and platelets.<sup>20</sup> However, methods for studying cell kinetics are not generally available in most clinics; consequently, ineffective hematopoiesis is inferred when there is no marrow hypoplasia.

#### **Causes**

The diverse causes of pancytopenia are listed in Table 56-1. Most of the diseases are discussed elsewhere, as indicated in the table;

Table 56-1 Causes of Pancytopenia

- 1 Disorders infiltrating the bone marrow
  - a Aleukemic leukemia (Chapter 47)
  - b Multiple myeloma (Chapter 52)
  - c Metastatic carcinoma (leukoerythroblastic blood picture Chapter 57) lymphoma (Chapters 50, 51)
  - d Myelofibrosis myeloid metaplasia (Chapter 57)
  - e Marble bone disease osteopetrosis (Chapter 57)
- 2 Disorders involving the spleen
  - a Congestive splenomegaly (Chapter 45)
  - b Lymphomas Hodgkin's disease non Hodgkin's lymphoma (Chapters 50 and 51)
  - c Infiltrative disorders Gaucher's disease, Niemann-Pick's disease (Chapter 42), Letterer-Siwe disease (Chapter 42)
  - d Infectious diseases kala-azar miliary tuberculosis syphilis
  - e Primary splenic panhematopenia\* (Chapter 42)
- 3 Vitamin B<sub>12</sub> or folate deficiency—pernicious anemia sprue etc (Chapters 14-15)
- 4 Disseminated lupus erythematosus
- 5 Paroxysmal nocturnal hemoglobinuria (Chapter 29)
- 6 Miscellaneous disorders (with cellular marrow)—overwhelming infection mycobacterial infections (some cases) brucellosis sarcoid pregnancy (some cases) some refractory anemias sideroblastic anemia (rarely) and perhaps drug sensitivity<sup>24</sup>
- 7 Aplastic or hypoplastic anemia
  - a Acquired
    - (1) Chemical and physical agents (Table 56-2)
      - (a) Agents that regularly produce aplasia if dose is sufficient—ionizing radiation, benzene, etc
      - (b) Agents only occasionally associated with hypoplasia—drugs
    - (2) Other causes of aplastic or hypoplastic anemia—certain viral infections (hepatitis, dengue) some mycobacterial infections, pregnancy, Simmond's disease, sclerosis of the thyroid
    - (3) Idiopathic
  - b Familial—Fanconi's constitutional pancytopenia pancreatic deficiency in children

therefore, only a few unusual causes and the aplastic anemias will be considered here.

### Disseminated Lupus Erythematosus<sup>22</sup>

Anemia, thrombocytopenia, or leukopenia is commonly present in patients with dissem-

inated lupus erythematosus.<sup>22,31</sup> Anemia is manifest in most patients during the course of this disease. Thrombocytopenia may be severe and bleeding phenomena are not unusual even as initial complaints.<sup>22</sup> Simultaneous depression of erythrocytes, platelets, and leukocytes is more unusual, being evident perhaps only in 5% of these patients. Moreover, the leukopenia, if present, is mild (rarely less than  $2.0 \times 10^9$  cells/ $1^{23}$ ), and neutrophils usually constitute at least 50% of the cells present. As a rule these patients can respond to infection with an increase in neutrophils and a shift to the left.<sup>34</sup> The bone marrow usually is cellular but may be hypocellular on rare occasions.<sup>22,31</sup> The diagnosis is suggested by symptoms and signs such as arthritic manifestations, skin lesions, and polyserositis, which often precede the appearance of hematologic manifestations.

### Miscellaneous Disorders

Severe overwhelming infection rather than being a direct cause of pancytopenia usually reflects the exhaustion of marrow reserves already depleted, eg, as a result of vitamin deficiency (B<sub>12</sub> or folate), alcoholism, the effect of drugs or chemicals to which the patient may be sensitive, or previous treatment with cytotoxic agents. The marrow in such subjects often is cellular but with few mature neutrophils present, and there is an apparent increase in immature forms, thereby giving the appearance of so-called "maturation arrest"; the bone marrow picture may even simulate that of acute leukemia (see page 1302). Pancytopenia has been reported occasionally in association with tuberculosis<sup>10,50</sup> and other mycobacterial infections such as *M. kansasii*.<sup>25</sup> Clinical features included fever, sweating, weight loss, lymphadenopathy, and splenomegaly. Macrocytosis and severely hypoplastic or aplastic bone marrow containing caseating tubercles were present in some patients while in others the marrow was cellular. Miliary infection involving the spleen and lymph nodes was the usual finding. Occasional apparent cures have followed splenectomy and appropriate antibiotic ther-

apy,<sup>15,50</sup> but more often the presence of tuberculosis represents only the coincidental occurrence of this infection in patients with leukemia or other dyscrasias.<sup>18</sup> Rarely pancytopenia has been reported in association with brucellosis,<sup>33</sup> sarcoid, pregnancy,<sup>305</sup> idiopathic sideroblastic anemia,<sup>29</sup> and refractory anemia, some of which conditions, after a variable period, may evolve into acute myelomonocytic leukemia, erythroleukemia, myelofibrosis, or aplastic anemia.<sup>33</sup>

### "Bicytopenia"

Commonly patients are encountered in whom only two of the formed elements are present in decreased concentration.<sup>2</sup> This may occur in association with most of the disorders listed in Table 56-1, either as a persistent finding or as pancytopenia is developing. Other examples can be found, eg, congenital rubella with thrombocytopenia and hemolytic disease in association with decreased megakaryocytes in an otherwise cellular marrow<sup>40</sup>; severe refractory anemia and leukopenia without thrombocytopenia in a man with *equine infectious anemia*.<sup>37</sup>

### Symptoms and Signs

The initial clinical picture in patients with pancytopenia varies widely. The onset is often insidious. Manifestations depend on the severity of the anemia, thrombocytopenia, or leukopenia. Other clinical features and simple laboratory findings reflect the underlying disease process and usually serve to reduce the number of possible diagnoses quickly. Thus the presence of splenomegaly is compatible with many of the conditions listed in Table 56-1 but calls attention in particular to the possibility of leukemia, the lymph node disorders, myelofibrosis, and congestive splenomegaly. The presence of enlarged lymph nodes further supports the possibility of leukemia, one of the lymphomas, or lupus erythematosus. On the other hand, lack of these signs and absence of evidence to suggest vitamin B<sub>12</sub> or folate deficiency should suggest

multiple myeloma or aplastic anemia. The presence of rouleaux on the blood smear or Bence Jones protein in the urine suggests myeloma. Immature erythrocytes and leukocytes in the blood smear (leukoerythroblastic blood picture, Chapter 57) suggest infiltrative disease in the bone marrow (eg, metastatic carcinoma, leukemia or myelofibrosis) except when there is greatly accelerated blood formation and destruction such as occurs in frank hemolytic anemia.

The anemia is usually normochromic and normocytic, but occasionally it is mildly macrocytic. The leukopenia usually is due to a reduction in the absolute number of cells of the myeloid series and thus there is relative lymphocytosis. However, if the reduction is sufficiently great, lymphocytopenia is found as well.

### Diagnosis

Difficulty in diagnosis arises when atypical features are encountered, for example, when a patient thought to have aplastic anemia is found to have a normally cellular or even hypercellular marrow. One explanation for such a contradictory finding is that the biopsy needle has entered an area in which the bone marrow is regenerating after severe damage; this has been shown to occur after benzol intoxication or irradiation (see page 1747). Another not uncommon dilemma arises when several marrow aspirations are found to be acellular in a patient thought to have leukemia. In most situations a larger marrow sample obtained by trephine or surgical biopsy will solve the problem. In a few conditions, such as congestive splenomegaly or "splenic panhematopenia," the diagnosis is arrived at largely by excluding the other possibilities. Finally, in a few patients no clearly defined syndrome can be recognized.<sup>53</sup>

### Treatment

The treatment of pancytopenia is dictated by the nature of the underlying disease.

## Aplastic Anemia

### History and Definition

The concept of aplastic anemia was introduced in 1888 by Ehrlich<sup>14</sup> who described a rapidly fatal case of severe anemia and leukopenia with associated fever, ulcerated gums, and menorrhagia in a young woman; the platelets were not described. At autopsy there was no active marrow and Ehrlich attributed this to primary depression of marrow function.<sup>14</sup> Chauffard, in 1904, introduced the term "aplastic anemia." Subsequently, case reports and reviews were published without clear definition or agreement concerning the criteria for this diagnosis.<sup>15</sup> In time it came to be recognized that cases similar to but with a more chronic course than that described by Ehrlich may be encountered and an association between aplastic anemia and exposure to a variety of chemical and physical agents ultimately began to be recognized. By 1934, aplastic anemia, although still not clearly defined, was described as a distinct clinical entity characterized by pancytopenia and thought to be the result of depressed bone marrow activity.<sup>15</sup> However, in most of the patients reported, the marrow was not aplastic. The authors suggested that "progressive hypocythemia alone should be sufficient reason for making the diagnosis, provided leukemia can be excluded," but the difficulty in differentiating aleukemic leukemia from uncomplicated marrow depression was well illustrated by the cases that were reported.

The term "aplastic anemia" has been used sometimes as essentially synonymous with refractory anemia<sup>7</sup> or even pancytopenia of any cause.<sup>16</sup> Other terms that have been proposed are *progressive hypocythemia*,<sup>15</sup> *aregeneratory anemia*, *aleukia hemorrhagica*, *pamyelophthisis*, *hypoplastic anemia*, and *toxic paralytic anemia*. In several reviews in the early 1950's<sup>1,5</sup> the name "aplastic anemia" was used only to refer to cases in which no evidence of primary disease capable of producing marrow suppression could be found; in many of these patients the marrow was hypoplastic.<sup>1</sup> As the result of a study of 39

cases we suggested, in 1959,<sup>44</sup> that the term "aplastic anemia" be reserved for cases in which pancytopenia exists, in which there is evidence of decreased production of all the elements of the blood formed in the marrow, including severe hypoplasia or aplasia of the marrow, and in which no evidence is found of a primary disease infiltrating, replacing, or suppressing active hematopoietic tissue. Some confusion persists, however, because patients are encountered in whom the clinical and blood pictures are consistent with a diagnosis of aplastic anemia but the bone marrow is not aplastic.<sup>1,53,114</sup> It is recognized that the morphologic structure of the bone marrow, particularly as seen in a single small aspiration or biopsy sample, does not necessarily accurately mirror total bone marrow function and that a clinical and blood picture resembling the acute disorder described by Ehrlich or even the more chronic forms will not always be accompanied by a completely fatty marrow. However, patients in whom occasional nucleated red cells as well as polychromatophilia and stippling, rather than the classical "aregenerative" picture, are present in the blood are better considered as having some other disorder.

### Pathophysiology

The basic defect in aplastic anemia appears to be a failure of blood cell production that involves erythrocytes, platelets, and leukocytes. It is not entirely clear whether some common stem cell population has been decimated or rendered incapable of repopulating the marrow cell mass (a "seed" or *stem cell deficiency*) or whether the "soil" or marrow environment is unsatisfactory for continued cell production (*micro-environment deficiency*).<sup>45</sup> Evidence can be cited to support either of these pathogenetic mechanisms. The success of marrow transplants in some identical twins<sup>79,4</sup> and the increased incidence of nuclear abnormalities in some patients with idiopathic marrow aplasia<sup>39,2</sup> and of chromosome abnormalities in those with Fanconi's anemia (page 1767), as well as the fact that defects have been found in all three cell lines

in patients with *paroxysmal nocturnal hemoglobinuria* and marrow hypoplasia (see page 958), suggest a defect in stem cells. In addition, the marrow content of stem cells capable of forming colonies on in vitro culture is reduced in patients with aplastic anemia.<sup>27</sup> On the other hand, the failure of marrow infusions to repopulate areas of heavily irradiated marrow (>4,000r) in animals,<sup>23</sup> failure of marrow to regenerate in man after more than 2500 to 3500 rads has been delivered,<sup>109,126</sup> and the marrow hypoplasia observed in starvation<sup>303</sup> and in graft-versus-host rejection<sup>310</sup> suggest that the marrow environment is important and in some instances may be unable to support marrow cell growth. Possibly stem cell deficiency occurs in some subjects, while environmental deficiencies predominate in others.

A classification of aplastic anemia is presented in Table 56-1, group 7.

## Acquired Aplastic Anemia

### Etiology

#### *Chemical and Physical Agents Producing Marrow Hypoplasia*

The chemical and physical agents producing marrow hypoplasia can be divided into two main categories, as shown in Table 56-2 and discussed in the following paragraphs.

AGENTS WHICH REGULARLY PRODUCE MARROW APLASIA WHENEVER A SUFFICIENT DOSE HAS BEEN GIVEN. The effects are more or less predictable and the changes observed in human subjects can be reproduced in experimental animals. Of these agents, benzene and ionizing radiation will be discussed here. Most of the remainder, which include a variety of agents used in cancer chemotherapy such as the nitrogen mustards, antimetabolites, and antimitotic agents (Table 56-2), are considered elsewhere (Chapter 55).

**BENZENE AND ITS DERIVATIVES.** Benzene has been known as a cause of fatal aplastic anemia since Santesson's description (1897) of four

cases in workers in a bicycle-tire factory.<sup>72</sup> Benzene ( $C_6H_6$ ) is a hydrocarbon that is obtained as a by-product in the manufacture of coke. It is also to be found in petroleum distillates, the amount depending in part on the composition of the crude petroleum from which the distillate has been derived.<sup>44</sup> Benzene is used as a solvent for rubber, gum, resins, fats, and alkaloids as well as in the manufacture of drugs, dyes, and explosives. It has been employed in many industries, including the manufacture of artificial leather, natural leather, enamels, rubber, waterproof fabrics, lacquers, shellac, paint removers, bronzing, silvering and gilding liquids, and batteries; in electroplating, lithography and photography, dry cleaning, and leather preparation; in the airplane, linoleum, and celluloid industries.<sup>83</sup> Certain petroleum fractions contain significant quantities of benzene and often are used to clean machinery parts or in cleaning grease from the hands. A benzene derivative (cymene) is present in the exhaust gases encountered in the sulfite pulp industry.<sup>73</sup> Benzene is volatile and consequently is readily absorbed by inhalation in badly ventilated rooms; it is poorly absorbed through the skin.<sup>79</sup> The maximum allowable vapor concentration for industrial usage has been 100 ppm,<sup>72</sup> but this is probably too high.<sup>44,79</sup> In spite of its wide recognition as a myelotoxic agent, benzene remains an important cause of hematopoietic damage, even in the home where it has been used in cleaning agents.

The classic picture of leukopenia, thrombocytopenia, and severe anemia represents only the severe and fatal form of poisoning by benzene. Among exposed workers the most common abnormality reported was anemia (48%). Next in frequency were macrocytosis (47%), thrombocytopenia (33%), and leukopenia (15%).<sup>80,81</sup> In other studies of workers making shoes under unhygienic conditions and exposed to benzene vapor, leukopenia was seen in 9.7%, thrombocytopenia in 1.8%, pancytopenia in 2.7%, and both leukopenia and thrombocytopenia in 4.6%.<sup>70</sup> Anemia was common (33%) but responded completely to iron therapy in the patients so treated. It

**Table 56-2. Chemical and Physical Agents Associated with the Development of Pancytopenia and a Hypoplastic Marrow**

- A Agents that regularly produce marrow hypoplasia and aplasia if a sufficient dose is given**
- 1 Benzene its derivatives (trinitrotoluene) and related agents
  - 2 Ionizing radiation (roentgen rays radioactive isotopes, atomic bombs, etc)
  - 3 Sulfur or nitrogen mustard and congeners (busulfan, melphalan cyclophosphamide, etc)
  - 4 Antimetabolites (antifolic compounds purine or pyrimidine analogues such as 6-mercaptopurine, thioguanine, cytosine arabinoside)
  - 5 Antimitotic agents (colchicine periwinkle alkaloids)
  - 6 Certain antibiotics (daunorubicin adriamycin)
  - 7 Other toxic agents (inorganic arsenic, dichlorovinylcysteine, estrogens)
- B Agents occasionally associated with hypoplasia or aplasia**

<i>Class of Compound</i>	<i>20 or More Reported Cases</i>	<i>Single or Very Few Reports</i>
Antimicrobial agents	chloramphenicol <sup>54</sup>	streptomycin, <sup>260</sup> penicillin <sup>54</sup> methicillin <sup>275</sup>
	organic arsenicals <sup>202</sup>	oxytetracycline, chlortetracycline, <sup>291</sup> sulfonamides <sup>44,289</sup>
	quinacrine <sup>211</sup>	sulfisoxazole (Gantresin), sulfamethoxypyridazine (Kynex) <sup>261</sup> amphotericin B <sup>251</sup>
Anticonvulsants <sup>225</sup>	methylphenylethyldantoin (Mesityl), trimethadione (Tridione)	methylphenylhydantoin (Nuvarone), <sup>221</sup> phenacemide (Pharicrone), <sup>226</sup> Dilantin <sup>445</sup> ethosuximide (Zarontin) <sup>221</sup>
Antithyroid drugs		carbethoxythiomethylglyoxaline (Carbimazole), <sup>254</sup> methylmercaptimidazole (Tapazole), <sup>274</sup> potassium perchlorate, <sup>265</sup> propyl thiouracil <sup>277</sup>
Antidiabetic agents		tolbutamide <sup>257</sup> chlorpropamide <sup>292</sup> carbutamide
Antihistamines		tripelenamina (Pyrbenzamine) <sup>264</sup>
Analgasics	phenylbutazone <sup>230,231</sup>	acetyl salicylic acid <sup>293</sup> indomethacin, <sup>254,261</sup> carbamazepine (Tegretol) <sup>250,272</sup>
Sedatives and tranquilizers		meprobamate, <sup>290</sup> chlorpromazine <sup>284</sup> promazine, <sup>44</sup> chlordiazepoxide (Librium), <sup>278</sup> mepazine <sup>44</sup>
Insecticides		chlorophanothana (DDT), <sup>281</sup> parathion, chlordane pentachlorophenol <sup>281</sup>
Miscellaneous	gold compounds <sup>242</sup>	acetazolamide (Diamox) <sup>289</sup> hair dyes <sup>251</sup> dinitrophenol, <sup>270</sup> thiocyanate, <sup>268</sup> bismuth, <sup>258</sup> 285 mercury, <sup>268</sup> colloidal silver <sup>268</sup> carbon tetrachloride <sup>288</sup> solvents <sup>44</sup>

seems probable that the anemia was an incidental finding and due to unrelated iron deficiency. Other manifestations of poisoning that have been observed are lymphocytopenia, increased reticulocyte count, eosinophilia, immature marrow elements in the circulating blood, leukocytosis,<sup>72</sup> and pseudo Pelger-Huet cells.<sup>70</sup> Evidence of increased blood destruction also has been reported. In one survey, serum bilirubin values were found to be elevated in a third of the subjects.<sup>81</sup> Data furnished to support the state-

ment that polycythemia may occur<sup>72</sup> are not convincing.

There are great variations in susceptibility to benzene poisoning.<sup>72</sup> Evidence of poisoning may appear in a few weeks or only after many years of exposure, or it may not be discovered until the onset of infection long after exposure has ceased. Any degree of exposure is potentially dangerous.

Like the blood picture, which may be of the regenerative or the hemolytic type instead of aplastic, the bone marrow may be found

to be hyperplastic rather than acellular and this can be the case even when the blood shows little evidence of regenerative activity. Extramedullary hematopoiesis has been observed<sup>72</sup> and the complete picture of myeloid leukemia has been described in a few patients.<sup>76,77,88</sup> More often, when extramedullary hematopoiesis has been present, marked splenomegaly and a blood picture of myelophthisic anemia have been found (page 1786).

When a benzene-olive oil mixture is injected in rats, the neutrophilic granulopoietic system is first stimulated.<sup>85</sup> The blood neutrophils have been observed to increase in number and there is hyperplasia of myelocytes in the marrow. Frequent subcutaneous injections may produce a leukemoid picture.<sup>72</sup> The myeloid hyperplasia is followed by destruction of these elements. Degenerative changes occur even more rapidly in the lymphatic tissue than in the bone marrow and lymphocytopenia occurs coincidentally. Erythropoietic tissue is more resistant, but hemolytic anemia develops when large doses are given. Eventually, hypoplasia follows degeneration of stem cells.

When marrow regeneration was studied in benzene-intoxicated and in normal rabbits, some of whose bone marrow had been extirpated, it was observed that, in the latter, sheets of primitive reticular cells and bone trabeculae, then fat cells, and finally myeloid tissue appeared as marrow regenerated.<sup>98</sup> In contrast, in the benzene-intoxicated animals, the extirpated marrow regenerated only to the point of formation of primitive reticular cells and fat cells. This would suggest that benzene may inhibit cell division and maturation beyond the level of the primitive reticular cell. Benzene has been shown to inhibit RNA and DNA synthesis by marrow cells.<sup>92</sup> In studies in which mitosis of living erythroblasts was observed, anomalies in chromosome distribution and other changes were found.<sup>96</sup>

Among substances related to benzene, trinitrotoluene is prominent as a cause of aplastic anemia; this agent may also produce hemolytic anemia. It has had wide use in industry.<sup>75,83</sup> Aplastic anemia also has been

reported following inhalation of fumes of various types of hydrocarbon-containing glues ("glue-sniffing")<sup>94</sup> and cutaneous and oral exposure to kerosene.<sup>82</sup> However, there is only circumstantial evidence that the aromatic compounds found in petroleum distillates, other than benzene, have myelotoxic properties.<sup>44,79,85</sup> Aplastic anemia also has been reported following exposure to heated and vaporized benzene hexachloride (lindane),<sup>86</sup> but this appears to be very unusual since little in the way of hematologic effects was noted in several exposed populations.<sup>90</sup>

**IONIZING RADIATION** The acute destructive effect of ionizing radiation on the bone marrow is well known, as is the fact that excessive exposure may result in severe and even fatal aplastic anemia.<sup>108</sup> Lesser grades of exposure lead to less serious or no detectable changes in the blood.<sup>110</sup>

The mode of action of radiation, the susceptibility of various tissues, and the effects of radiation on the blood and bone marrow were discussed in Chapter 55. Here only certain aspects of the effects of accidental or unsuspected exposure to radioactive substances will be considered.

The use of thorium dioxide as a diagnostic aid in the form of Thorotrast was followed many years later in a few instances by the development of aplastic anemia,<sup>107,118</sup> leukemia, and primary malignant disease in the liver,<sup>102,120</sup> the lung, and at the site of injection.<sup>115</sup> The late effects of radium and mesothorium<sup>100</sup> are related to changes in the bones (radiation osteitis, neoplasms in or near bone). Only minor degrees of anemia have been observed and rarely aplastic anemia. Acute radium poisoning, like that in the radium dial workers, is accompanied by very striking changes in the blood (see below). A high incidence of leukemia and cancer has been observed in persons exposed to ionizing radiations and aplastic anemia has been reported in a few survivors.<sup>112,114</sup>

The effects of continuous internal irradiation were described many years ago in radium dial workers by Martland.<sup>116</sup> In these individuals, injured by the ingestion of radium

through the habit of wetting their brushes by mouth, severe macrocytic anemia with megakaryoblasts in the circulating blood, leukopenia, and relative lymphocytosis developed. The femur bone marrow was dark red and showed primitive red cells and leukocytic hyperplasia, as well as numerous megakaryocytes. In a number of subjects there was necrosis of the jaw and buccal lesions similar to those found in patients with acute leukemia. Low-grade osteitis, replacement fibrosis of the marrow, and osteogenic sarcoma were also encountered. In some of the affected workers, death occurred as late as four to six years after leaving their occupation. In experimental radium poisoning<sup>122</sup> the first effect of radioactive substances given orally was the production of changes in the teeth, mouth, and jaws, changes similar to those found in dial workers.<sup>104</sup> Hyperplastic marrow, similar to that described by Martland, and macrocytic anemia have also been noted in human beings and animals subjected only to external roentgen radiation.<sup>108,110</sup>

The practice of making regular blood counts in persons occupationally exposed to radiation has little to justify it.<sup>119</sup> Degrees of radiation exposure twenty times greater than the maximal permissible dose may produce a real drop in neutrophils or lymphocytes, but the change is slight and serious aplastic anemia has been observed to occur without necessarily being preceded by much decrease in leukocytes.<sup>119</sup> Regular physical measurement of the doses received by the use of film badges and other methods is a much more practical procedure in most situations.

**OTHER TOXIC AGENTS** *Inorganic arsenic* in the form of potassium arsenite once was employed in the treatment of leukemia because of its consistent depressing effect on the leukocyte count. In experimental studies, decreased red cell production resulted from the administration of arsenic and arsenious acid.<sup>120</sup> In inorganic arsenic poisoning, granulocytopenia,<sup>121</sup> anemia, and, less often, thrombocytopenia<sup>120</sup> occur and basophilic stippling is a prominent finding.<sup>128</sup>

The feeding of *extracted soybean meal* has

been shown to produce aplastic anemia in cattle and several other species,<sup>141</sup> apparently as a result of a toxic product (*dichlorovinylcysteine*) formed by the interaction of trichloroethylene used to extract the oil and cysteine in the beans.<sup>142</sup> Also very large doses of *estrogens* have produced hypoplastic anemia in dogs.<sup>135</sup>

**AGENTS OCCASIONALLY ASSOCIATED WITH MARROW HYPOPLASIA OR APLASIA. HISTORY.** There is an ever-increasing number of compounds (Table 56-2) that are only occasionally associated with bone marrow hypoplasia or aplasia. Not only is their number great, but their deleterious effect is unpredictable. The basis for assuming that they are the cause of untoward reactions is circumstantial, since it is only when a particular drug has been associated with some adverse reaction repeatedly that an etiologic relationship can be strongly suspected. For example, suspicion that the occurrence of aplastic anemia and the taking of chloramphenicol might be more than coincidental<sup>184</sup> led to the chain of events that culminated in the establishment of the Adverse Reactions Registry of the American Medical Association. From 1949 until 1952, when its use was unrestrained, chloramphenicol was the drug most frequently associated with the development of aplastic anemia in the United States.<sup>41</sup> A sharp decrease in the total number of cases appearing annually followed public warning of the hazard in 1952, but this was of brief duration because of denials of a possible relationship. The number of cases reported to the Registry rose progressively to a peak of 83 cases in the year 1959. Since then in the U.S.A. there has been a progressive decrease.<sup>56</sup>

Experience with chloramphenicol illustrates well the nature of the problem involved in adverse reactions to drugs. Where one deals with a reaction the incidence of which is very low, it is natural that there should be skepticism concerning the etiologic relationship between the drug and the reaction. Furthermore, it is difficult when examining case reports to check the validity of the his-

tory of drug intake or the hematologic diagnosis, and patients treated with one drug are likely to have received one or more other drugs. Thus to separate the potentially noxious from the innocent drugs is difficult. However, in an analysis of drugs reported to the AMA Registry as being associated with the development of pancytopenia, chloramphenicol was the drug most commonly associated with this reaction and in a striking proportion of instances it was the only drug given, or it was given with drugs not known to be toxic (Fig. 56-1). The contrast between the reports involving chloramphenicol and, for example, sulfonamides is illustrated in Figure 56-1. In the greater proportion of instances in which sulfonamides were named, these drugs had been given together with a potentially toxic one. This would imply that the sulfonamides were not etiologically related to the reaction observed.

The proportion of reports for a specific dyscrasia in relation to a particular drug also has been helpful in the analysis of data available to the Registry. Of 2149 cases reported

to June 30, 1964, 32.2% were concerned with pancytopenia, 17.2% with thrombocytopenia. Of the blood dyscrasias attributed to chloramphenicol, however, 70.3% were cases of pancytopenia, and only 6.5% were thrombocytopenias. Such a disproportionate concentration of reports of a specific dyscrasia in relation to a drug is further reason to suspect an etiologic relationship. In the same analysis, as many as 87.3% of the reports concerning quinidine referred to thrombocytopenia and only 3.2% reported pancytopenia. This strongly suggests a relationship of quinidine to thrombocytopenia; in the case of quinidine, there is evidence of another type incriminating it as an etiologic agent in thrombocytopenia (page 1092)

**MECHANISMS OF TOXICITY** From a study of case reports of aplastic anemia associated with drug administration, it seems clear that the observed ill effect is a result of individual sensitivity or susceptibility since no clear association with the amount of drug taken or with frequent or excessive usage has been

Fig 56-1. Numbers of cases of aplastic anemia and erythroid hypoplasia reported to the Registry on Adverse Reactions, Council on Drugs AMA (From Wintrobe,<sup>36</sup> courtesy of the author and Journal of the Royal College of Physicians)

demonstrated. As yet, no reliable method for predicting drug sensitivity has been devised, and no inherited enzymatic defects such as those resulting in hemolytic anemia on exposure to certain drugs (page 779) have been discovered to explain the individual sensitivity. Attempts to produce similar changes in animals have met with failure.

**INCIDENCE** The incidence of aplastic anemia associated with drug administration is difficult to determine. In respect to quina-crine (Atabrine), when a large number of soldiers were given this drug for malaria prophylaxis, aplastic anemia developed in about 1 in 25,000 man-years or in 1 to 50,000 persons<sup>211</sup> as compared to 1 in 500,000 soldiers not so treated.<sup>187</sup> In regard to chloramphenicol, the risk of developing fatal aplastic anemia may be in the range of 1 in 60,000<sup>182</sup> or 1 in 20,000<sup>187</sup> i.e., about 13 times the frequency of aplastic anemia in the population not so exposed.<sup>187</sup> For most other drugs, the incidence is unknown since the population at risk has not been determined. Of 1067 cases of aplastic anemia reported to the American Medical Association Council on Drugs, 376 of the patients had received chloramphenicol and this was the only drug given to 173 of the group.<sup>56</sup> Compared to chloramphenicol, other drugs appear to be relatively infrequent offenders (Fig. 56-1). A few drugs have been reported as being associated with aplastic anemia in 20 or more persons, while a large number have only rarely been reported as being associated with this dyscrasia (Table 56-2). Many of these drugs may also be associated with the occurrence of neutropenia alone (page 1292), thrombocytopenia (page 1084), or "bicytopenias."<sup>2</sup> In a number of instances these disorders have been reported more often than has aplastic anemia. For example, phenothiazines, sulfonamides, antihistamines, and anti-thyroid drugs are more commonly associated with neutropenia than with aplastic anemia, whereas chloramphenicol<sup>151</sup> and the organic arsenicals have been more frequently associated with aplastic anemia.

*The agents only occasionally associated with*

aplastic anemia can be considered in groups according to drug class (Table 56-2). Only the more frequent offenders will be discussed in any detail.

**CHLORAMPHENICOL** An analysis of 408 cases of chloramphenicol-associated, non-oculoplastic depression of one or more blood cell types reported to the Registry showed persons of all ages to be affected, there being a broad adult range of from 25 to 65 years old and a childhood peak.<sup>182</sup> Until the menopausal age, 70% of the subjects were females. These trends are at least in part explained by patterns of occurrence of diseases for which chloramphenicol is often given. The significance of a high incidence among Caucasians and, in particular, north Europeans, is unclear, but may be related to the care with which patients have been studied and to the degree of willingness to report blood dyscrasias. In 75% of the reported patients, all three blood cell types were depressed and marrow hypoplasia was found. Chloramphenicol had been given in most instances for treatment of, or prophylaxis against, infection, and in many instances the indication for its use was of dubious validity. No clear relationship could be established between the development of the dyscrasia and previous exposure to the drug, the dose employed, or continuous, as compared with intermittent, administration. In 50% of the subjects, evidence of reaction appeared within 38 days of the last dose, in 22% during therapy, and in 10% after 130 days. In an occasional patient, aplastic anemia developed after administration of as little as 2 g of drug to a patient never before so treated.<sup>185</sup> The overall mortality rate was about 50%, half of the deaths occurring within 50 days of the reaction. Variables speaking for a more favorable prognosis were (1) fewer blood cell types depressed; (2) non-Caucasian race; (3) development of reaction during therapy or shortly thereafter; and (4) cases treated with large daily doses.

As already noted, the pathogenesis of chloramphenicol-associated blood dyscrasias is obscure. Although not all investigators agree, most believe that two types of reac-

tions occur, a reversible suppression of erythropoiesis and irreversible aplasia.<sup>152,190,193</sup> If so, it is very possible that they are unrelated.

Reversible bone marrow suppression primarily involving erythropoiesis occurs in about 50% of patients to whom chloramphenicol is given in large doses. Increased serum iron, reticulocytopenia, and a falling level of hemoglobin may be found.<sup>162,175,177</sup> Ferrokinetic studies made at this time reveal prolonged half-disappearance time of plasma iron, decreased uptake of radioiron by the bone marrow, increased uptake by the liver, and failure of radioiron to appear in circulating red cells for eight days or more.<sup>175</sup> Thus, suppression of heme and hemoglobin formation<sup>189</sup> has been demonstrated. Less often, neutropenia and thrombocytopenia may develop.<sup>170,175</sup> The marrow is not characterized by hypoplasia, and abnormal sideroblasts have been seen in the marrow in some patients at this stage.<sup>150</sup>

A striking finding in the bone marrow is vacuolization of the nucleus and cytoplasm of the erythroblasts<sup>177</sup>; similar changes occur in the granulocytic series (Fig. 56-2) although less frequently.<sup>162</sup> These toxic effects usually have been observed between 11 and 18 days after the antibiotic was started and have been correlated with elevated levels of serum chloramphenicol concentration<sup>180</sup> and impaired clearance of the drug.<sup>185</sup> If the drug is withdrawn at this point the reaction is reversible.<sup>180</sup> It is reported that susceptibility to this form of chloramphenicol toxicity can be predicted if clearance of a single 500 mg dose of drug is found to be delayed.<sup>185</sup>

It was claimed that the administration of l-phenylalanine to children caused the cellular vacuolization to disappear and remain absent in spite of continued administration of chloramphenicol,<sup>185</sup> but a similar effect was not noted in adults.<sup>160</sup>

This reversible and primarily erythropoietic toxicity from chloramphenicol ap-

Fig. 56-2. Vacuolated erythroblast and myelocyte in the marrow of a patient with aplastic anemia apparently due to chloramphenicol. (Courtesy of Dr. Ralph Wellerstein)

pears to be a pharmacologic action of the drug. Its biochemical basis has been the subject of some controversy. Initially it was proposed that chloramphenicol is bound to messenger RNA and thus ribosomal protein synthesis is blocked.<sup>159,161</sup> However, subsequent studies could not confirm this,<sup>160</sup> but provided evidence that mitochondrial protein synthesis and mitochondrial ultrastructure of both erythroid and myeloid cell precursors are adversely affected by the usual clinical levels (10 to 16  $\mu\text{g/ml}$ ) of chloramphenicol.<sup>161</sup>

Chloramphenicol also inhibits the post-phagocytic respiratory burst in human leukocytes, perhaps by inhibiting NADH oxidase activity<sup>162</sup>; in rabbits a chloramphenicol-induced defect in erythroid precursor respiration was reported to be due to a depletion of mitochondrial cytochromes.<sup>158</sup> There also is evidence that the drug retards the bio-transformation of drugs such as tolbutamide, diphenylhydantoin, and dicoumarol by inhibiting the microsomal drug-metabolizing system in the liver.<sup>153,155</sup> The latter observations may explain the impression that patients chronically ill with liver disease are especially likely to develop chloramphenicol toxicity.<sup>162</sup>

The relationship of such erythropoietic depression by chloramphenicol to aplastic anemia is unknown. Some believe that erythropoietic depression is a basically different and reversible toxicity.<sup>191,194</sup> However, the occasional production of pancytopenia by high-dose therapy<sup>170</sup> or by the more toxic chloramphenicol analogues (Fig. 56-3),<sup>190</sup> the production of vacuoles in myeloid as well as erythroid forms, and the evidence that more immature cell forms such as primitive erythroblasts<sup>191</sup> seem more sensitive to chloramphenicol toxicity than mature cell forms suggest that similar toxicity at a stem cell level may be the cause of aplastic anemia. The question remains unanswered.

*Severe and often irreversible bone marrow aplasia*, frequently resulting in death, is the second type of reaction to chloramphenicol. As already mentioned, there is equivocal evidence that this reaction is related clinically or pathogenetically to the reversible, mainly

erythropoietic lesion described above. Individual susceptibility seems a more likely basic mechanism. The concordant development of aplastic anemia in one set of identical twins<sup>173</sup> and the development of aplastic anemia in one of another set of twins with thrombocytopenia in the partner<sup>156</sup> suggest the presence of an heritable predisposition that may have to be present in homozygous form before susceptibility is manifest.<sup>152</sup> Since, in most instances, aplastic anemia becomes evident only after use of the drug has been discontinued and since a long period of aplasia follows even in those patients who recover, some type of damage that lingers long after the last traces of drug have disappeared must be considered. Damage to a high percentage of stem cells has been postulated.<sup>152</sup> Damage to the chromosomes of human blood leukocytes cultured *in vitro* in the presence of chloramphenicol in usual therapeutic concentrations (10 to 40  $\mu\text{g/ml}$ ) provides support for this concept.<sup>171</sup>

There is no evidence that monitoring the effects of chloramphenicol by means of repeated blood counts will reduce the incidence of chloramphenicol-associated aplastic anemia. Far more important is the initial judgment and restraint of the physician who prescribes the drug. With this, as with other potentially harmful therapeutic agents, the physician must weigh the risk against the possible gain. All too often chloramphenicol has been prescribed for trivial reasons.

**ORGANIC ARSENICALS.** Organic arsenicals (arsphenamine, neoarsphenamine, mapharsen, etc.), once the agents of choice in the treatment of syphilis, are known to cause a variety of blood dyscrasias, more commonly thrombocytopenia or neutropenia but also aplastic anemia.<sup>200,201</sup> The development of aplastic anemia was unrelated to the dose administered or the duration of therapy, and the proportion of patients who developed such anemia was small. However, because of the once widespread use of arsenical therapy, more than 50 cases of aplastic anemia associated with such treatment were reported.<sup>204</sup> Sulfarsphenamine was probably the most

Fig 56-3. The effect of a chloramphenicol analog on serum iron and peripheral blood counts. Similar effects are seen with chloramphenicol itself. IBG denotes iron binding globulin. (From Weisberger,<sup>100</sup> courtesy of the author and the Journal of the American Medical Association.)

dangerous and Mapharsen the least toxic of the agents employed. Cross-reactivity between agents was not always demonstrable and it is not clear whether the toxic effect

was due to the benzene ring, the arsenic, the combination, or to sensitization. Danger signals in patients receiving these drugs were thought to be itching, skin rash, ready bruising.

ing, or fever or malaise appearing soon after injection.<sup>205</sup> The use of BAL did not prove beneficial in the few patients so treated.<sup>206</sup>

**QUINACRINE (ATABRINE).** Fifty-seven fatal cases of aplastic anemia secondary to the use of this drug for malaria suppression were seen in the South Pacific during World War II. As mentioned above, the incidence was estimated at 1 in 20,000 as compared to much lower levels (1 in 500,000) in troops in other theaters not so treated.<sup>211</sup> Aplastic anemia has also been reported in patients with discoid lupus treated with quinacrine.<sup>210,217</sup>

The mechanism of quinacrine toxicity is unknown. However, in rabbits the drug is concentrated in the marrow and lymphoid tissues from which its disappearance is considerably delayed as compared to its disappearance from the blood; also human marrow cells concentrate the drug *in vitro*.<sup>215</sup> Quinacrine suppresses leukocyte respiration *in vitro*<sup>214</sup> and leukocytes from patients treated with a related drug (chloroquine) were found to contain myelin figures (perhaps autophagic vacuoles) when examined with the electron microscope.<sup>213</sup>

**ANTICONSULSANTS** More than 48 cases of aplastic anemia associated with anticonvulsant drug therapy, especially methylphenylhydantoin (Mesantoin) and trimethadione, have been reported.<sup>220</sup> The onset of the anemia occurred as early as 2 weeks or as long as 30 months after starting treatment, but in most instances after 4 to 13 months. There was no relation to age, sex, or drug dosage.<sup>225</sup>

The mechanism of the toxic effect of these drugs is unclear. In one patient with pure red cell aplasia due to diphenylhydantoin the dyscrasia disappeared after drug withdrawal and recurred on two subsequent occasions when therapy was reinstituted for 17 and 32 days, respectively.<sup>445</sup> Additional studies in this patient suggested that the drug interfered with deoxyribotide formation in erythroid precursors, thereby inhibiting DNA synthesis.<sup>470</sup>

**PHENYLBUTAZONE.** The number of reported cases of aplastic anemia associated with use of this drug is difficult to determine but is at least 35 to 40.<sup>5,23,233</sup> Neutropenia is a much more frequent toxic effect than is aplastic anemia, but it has been claimed that the incidence of severe toxic reactions of all kinds is low in patients treated with doses of less than 200 mg/day.<sup>235</sup> The mechanism of action is unclear but has not been carefully studied.

**GOLD.** When gold compounds were in popular use for the treatment of rheumatoid arthritis and to a lesser extent for lupus erythematosus and tuberculosis, toxic effects were frequent, occurring in as many as 42% of one large series of 900 patients.<sup>241</sup> However, hematologic toxicity was noted in less than 5% of patients, and thrombocytopenia and granulocytopenia were more common than aplastic anemia. Nevertheless, the fatality rate in aplastic anemia due to gold was high, only 4 of 20 patients surviving,<sup>241</sup> and several patients were treated with BAL without perceptible benefit.<sup>240</sup> An increase in the use of gold in the treatment of rheumatoid arthritis seems likely as a result of the demonstration of its effectiveness in double blind trials, and the appearance of new cases of associated blood dyscrasias can be expected.<sup>242</sup>

**OTHER DRUGS AND AGENTS.** In addition to the above-named drugs, a wide variety of agents has been reported only very rarely as being associated with aplastic anemia. Many of these are listed in Table 56-2.

### *Other Causes of Aplastic or Hypoplastic Anemia*

Pancytopenia with aplastic or hypoplastic marrow has been reported occasionally in association with such conditions as *mycobacterial infection*<sup>15</sup> and, with increasing frequency, in infectious *hepatitis*.<sup>30,32,41,43</sup> Several varieties of dengue type *virus infections* in Southeast Asia have been reported to be associated with hypoplastic anemia,<sup>300</sup> and

about 50 cases were reported in association with pregnancy, most of the subjects improving after delivery or abortion.<sup>305,313</sup> Rare cases have been reported in association with sclerosis of the thyroid gland,<sup>308</sup> *Simmonds' disease*,<sup>302</sup> anorexia nervosa,<sup>311</sup> and graft-versus-host (runt) disease.<sup>307</sup> Marrow hypoplasia secondary to the ingestion of *contaminated grain* has been reported in Russia and was thought to be due to a toxin (perhaps a coumarin compound) produced by a mold.<sup>44</sup>

### "Idiopathic" Aplastic Anemia

Although one may search carefully for a possible etiologic agent in cases of pancytopenia, there remain approximately 50% of cases in which no cause is found or suspected.<sup>44,370</sup>

### Symptoms and Signs

In the majority of patients the initial symptoms of acquired aplastic anemia are manifestations of anemia and/or bleeding, but fever or infection are not uncommon.<sup>54</sup> The onset is insidious. The symptoms and their character depend on the rapidity with

which the anemia progresses and whether or not complicating infections and hemorrhage develop. Infection and hemorrhage, in turn, depend in part on the degree of granulocytopenia and thrombocytopenia. If the course is rapid, fever and symptoms attributable to anoxemia arise. If it is slow, progressive weakness and fatigability are the chief complaints until the thrombocytopenia becomes well marked, when bleeding from the nose, mouth (Fig. 56-4), or gastrointestinal tract, menorrhagia, or purpura develops. In general, however, purpura is not the most conspicuous feature. Ulcerations in the mouth and pharynx or low-grade cellulitis in the neck appear late, as a rule. In idiopathic cases the illness is often dated from an attack of some common type of febrile disorder. In the secondary forms, symptoms may develop some weeks or even several months following exposure to the causative agent. The first sign of benzene poisoning may appear with the onset of an infection, long after exposure has ceased.<sup>72</sup>

A waxy pallor is usually well marked by the time attention has been drawn to the illness. The yellowish tint of pernicious anemia is lacking. Weight loss is unusual. There may be bruises or purpuric spots in the skin,

Fig 56-4. Bleeding gums in a patient with aplastic anemia

but these are often inconspicuous in relation to the degree of thrombocytopenia. Hemorrhages may be noted in the eyegrounds. Splenomegaly is so unusual that, when the spleen is palpable, "aleukemic" leukemia or some other condition that may simulate aplastic anemia should be looked for. It should be noted, however, that, in a few patients with benzene poisoning,<sup>72</sup> the spleen was found to be enlarged. The tongue shows no papillary atrophy. Changes in the nervous system are found only when hemorrhage has occurred there, although there may be some complaint of paresthesias in this as in other forms of anemia. The skin may show a brownish pigmentation.<sup>7</sup>

### *Blood Changes*

As a rule, the red corpuscles are more or less normal in appearance in spite of the severity of the anemia. Polychromatophilia, stippling, and nucleated red corpuscles are usually not found and the uncorrected reticulocyte count is normal or low.<sup>54</sup> In some instances, however, the anemia has been macrocytic, there has been moderate anisocytosis and poikilocytosis,<sup>325</sup> and immature red cell forms have been reported.<sup>45</sup> The finding of young erythroid forms suggests an error in diagnosis for, even in patients in whom the bone marrow seemed to be hyperplastic, the circulating blood often gave no sign of regeneration.

The hemoglobin may be as low as 7 g/dl and the volume of packed red cells 0.2 l/l or lower when the patient is first seen.<sup>54</sup> At the same time there usually is leukopenia and thrombocytopenia. The leukocytes formed in the bone marrow are affected chiefly and thus the smear may contain as many as 70 to 90% lymphocytes. The leukocyte count may, however, be as low as  $1.5 \times 10^9/l$  or even  $0.15 \times 10^9/l$  and thus absolute lymphocytopenia is present as well. In patients in whom immature erythrocytic forms have appeared in the circulating blood, occasional immature myeloid leukocytes have been observed, but one would hesitate to make the diagnosis of aplastic anemia in such patients.

The bleeding time is usually moderately prolonged and the blood clot retracts poorly when thrombocytopenia is present. Coagulation parameters generally are normal. The fragility of the red corpuscles is normal.

The serum iron usually is elevated and the iron-binding protein saturated. Free erythrocyte protoporphyrin has been found to be increased.

Ferrokinetic studies in a patient with typical aplastic anemia are illustrated elsewhere (Fig. 4-10, page 166). The plasma radioiron clearance rate ( $t_{1/2}$ ) is prolonged, there is decreased uptake of radioiron by the marrow and an increase in liver and spleen uptake, whereas the incorporation of iron into circulating erythrocytes is decreased. Red cell life span may be somewhat shortened,<sup>325,327</sup> but evidence in the plasma, urine, and stools of increased blood destruction is lacking. In some patients, evidence of splenic sequestration of red cells has been reported.<sup>325</sup> In some of the other pancytopenic states, more variable results for plasma iron clearance and different ferrokinetic parameters have been reported<sup>4724</sup> and these may help in distinguishing such cases from aplastic anemia.

Hemoglobin F levels may be elevated in children with aplastic anemia and a separate population of hemoglobin F-containing erythrocytes can be identified in blood smears stained by the acid elution method.<sup>322</sup> Presumably such cells are produced by a clone of cells formed in an attempt to compensate for the severe anemia. In one series of children with acquired aplastic anemia, most of those with hemoglobin F levels greater than 400 mg/dl of red cells survived, whereas the majority with levels less than this died.<sup>322</sup> However, later studies did not confirm this observation.<sup>371</sup>

That granulopoiesis may be qualitatively as well as quantitatively abnormal is suggested by the finding of abnormal granulation in the neutrophils and high leukocyte alkaline phosphatase.<sup>375</sup>

Erythropoietin levels are markedly increased in patients with hypoplastic or aplastic anemia.<sup>329</sup>

## Bone Marrow

In patients with the classical type of acquired aplastic anemia the material obtained on sternal puncture consists chiefly of mature red corpuscles. The majority, even 60 to 100%, of the nucleated cells are lymphocytes. Such a finding makes it advisable to obtain a larger specimen, by biopsy, in order to be sure that one has obtained true bone marrow and not blood and also to see how fatty the marrow is. However, the most important bone marrow finding is the proportion of cells that are nonmyeloid and are not erythroblasts, since the proportion of such cells was found to be directly related to mortality.<sup>51,371,351</sup>

In marrow biopsy specimens from patients with typical aplastic anemia, only yellowish-white material, consisting chiefly of fat, fibrous tissue, and lymphocytes, is seen (Fig. 56-5). Marrow that appears red macroscopically may be found to be composed largely of extravasated blood and shows little evidence of regeneration. However, as pointed out previously, this classic picture is not always found in cases that otherwise seem to fit the category of aplastic anemia. In some patients there may be a preponderance of lymphocytes. In still others,<sup>35,53</sup> but especially in those with benzene poisoning<sup>72</sup> and in some who have had internal<sup>116</sup> or external<sup>114</sup> irradiation, the marrow has been hyperplastic. It is difficult to give the relative numbers of patients with aplastic, hypoplastic, normal, or hyperplastic bone marrow. This depends largely on the definitions and criteria used in diagnosis and has varied greatly in different series of subjects.<sup>355</sup>

## Diagnosis

From the hematologic standpoint, the characteristic triad is anemia, leukopenia, and thrombocytopenia. However, as outlined in Table 56-1, the causes of pancytopenia are numerous and those other than aplastic anemia must be ruled out before the diagnosis of aplastic anemia is made. The finding of lymphadenopathy or splenomegaly makes a

diagnosis of aplastic anemia very unlikely although, as mentioned earlier, slight splenic enlargement has been described in some patients (even 10% of one series<sup>54</sup>), especially after repeated transfusions. In addition to a thorough physical examination, which must include rectal examination and careful palpation of all the bones for tenderness, extensive radiographic studies may be required to rule out the possibility of lesions in bones or tumors not evident on physical examination. Examination of the urine cannot be overlooked as it may give evidence of multiple myeloma or of renal carcinoma. If fever is present, conditions such as Hodgkin's disease must be considered even though fever of slight or even moderate degree may occasionally accompany aplastic anemia, especially the more fulminating forms. A remote possibility is military tuberculosis (page 1742).

The finding of immature forms of the red or white series in the circulating blood is strong evidence against aplastic anemia, although here again exceptions have been reported. In patients in whom the anemia is macrocytic rather than normocytic and in whom some signs of red cell regeneration are present, real difficulty may be encountered. The possibility of pernicious anemia can be ruled out by the absence of glossitis, achlorhydria, or neural involvement, by the lack of pigmentary evidence of increased blood destruction, by the absence of true megaloblasts in the bone marrow, and, if the diagnosis is still in doubt, by the serum B<sub>12</sub> level or the Schilling test, as well as by the failure of appropriate therapy. Other forms of megaloblastic anemia are discussed on page 574. The possibility of hemolytic anemias should be excluded; for example, paroxysmal nocturnal hemoglobinuria may be mistaken for aplastic anemia. In aplastic anemia, the leukopenia is characteristically due to neutropenia. If all types of leukocytes are reduced in number or if lymphocytes are reduced to a greater degree than the neutrophilic series, Hodgkin's disease and even disseminated lupus erythematosus must be considered.

Thorough inquiry must be made concern-

Fig 56-5 Sections of bone marrow from patients with aplastic anemia compared with those of normal subjects

A Normal sternal marrow. Note the presence of disseminated erythropoietic foci (small hyperchromatic cells) and several scattered megakaryocytes (large cells with abundant cytoplasm).

B, Marked hypoplasia. Small foci of sparse cellularity composed of lymphoid or erythropoietic elements are observed.

C Moderate hypoplasia. An overall reduction in cellularity is apparent, the degree of cellular pleomorphism seen in this photograph represents the presence in reduced numbers of both myeloid and erythroid elements in various stages of maturation. A focus of small lymphocytes is present.

D Higher magnification of the lymphoid follicle present in C. Small lymphocytes predominate. The larger cells with more abundant cytoplasm are primitive reticular elements. (From Scott, Cartwright, and Wintröbe "courtesy of the authors and Williams & Wilkins Co.)

ing possible exposure to potentially toxic agents, either at the patient's place of work or at his home, in his pursuit of hobbies, or through medication whether prescribed by his physician or self-administered. The number of agents that may damage the hematopoietic system is large (Table 56-2) and growing.

The presence of only minimal neutropenia and thrombocytopenia should cause one to consider seriously the presence of some underlying chronic disease such as one of the conditions discussed in the first part of this chapter. A form of anemia that may be mistaken for aplastic anemia is that associated with chronic renal disease because this ane-

mia is notoriously unresponsive to therapy and the manifestations of the renal disease may be overlooked. A diagnosis of "pure red cell" aplasia (page 1769) must be made with caution for such cases are rare.

The diagnosis of aplastic anemia is one that is made largely by exclusion. Even when bone marrow puncture yields little marrow, the diagnosis is not certain for, from some patients with leukemia or with metastatic disease of the bone marrow, it may be difficult to withdraw any diagnostic material. Marrow puncture, even when repeated at several sites, may be misleading; we have demonstrated active marrow by surgical biopsy even when puncture repeatedly yielded very few cells. Needle biopsy of the bone marrow (page 66) is easily performed and often extremely helpful (Fig. 56-5).

Bizarre normoblastic chromatin or megaloblastoid cells are noted in patients with the di Guglielmo syndrome (page 1474) and these may alert one to this diagnosis even before the preponderance of early leukocytic forms characteristic of acute leukemia becomes evident. Similar chromatin abnormalities are present in patients with Fanconi's anemia<sup>132</sup> (page 1767). The finding of abnormal sideroblasts suggests sideroachrestic anemia (page 678), while extensive fibrous tissue, tumor nodules, or granulomas may suggest myelofibrosis, myelophthisic anemia, or other disorders (Chapter 57).

The differentiation of thrombocytopenic purpura (page 1071) should cause no difficulty. Although there may be considerable similarity on clinical grounds, the anemia that may be found in thrombocytopenic purpura is only proportional to the degree of blood loss. The leukocyte count should be normal or increased and signs of red cell regeneration may be found if there has been much loss of blood. Likewise "agranulocytosis" (page 1290) may have to be considered on clinical grounds, but in this condition anemia is slight or absent and thrombocytopenia is not found. Occasionally, as illustrated in Figure 56-6, only anemia or leukopenia, thrombocytopenia, or "bicytopenia" may be the first pre-

senting sign, only to be followed ultimately by pancytopenia with a hypocellular or acellular marrow.

The estimation of red cell production by means of ferrokinetic studies (page 164) provides data that are useful as an indication of decreased erythropoiesis, but this requires considerable time and effort and cannot be regarded as an essential diagnostic tool. Sometimes, however, it is useful to measure red cell survival with <sup>51</sup>Cr and to determine whether there is excessive destruction in the spleen.

### Treatment<sup>396</sup>

Treatment involves (1) a thorough search for a possible cause and prohibition of further exposure to a suspected drug or other toxic agent even if the evidence is not very impressive; (2) maintenance of hemoglobin levels by blood transfusion; (3) prevention and management of hemorrhage and infection; (4) attempts to stimulate hematopoiesis and marrow regeneration; (5) evaluation of the possible role of the spleen in the destruction of transfused red cells or platelets, and the removal of this organ if the evidence suggests that this may be wise and the patient can tolerate the procedure; (6) possible marrow transplantation in carefully selected patients.

### Avoidance of Further Exposure

Although it is obvious that the first requirement is the avoidance of further exposure to an etiologic noxious agent, this is sometimes overlooked or the cause is not recognized. It is essential that a thorough and systematic search be made. Ideally the noxious agent, if still present, should be removed from the body, but this is not always possible. When the toxic agent is an arsenical, gold, or certain radioactive isotopes, BAL (British anti-Lewisite), penicillamine, or other chelating agents may be tried. These agents will enhance excretion of metals<sup>365</sup> but clinical benefit is variable<sup>206,210,241</sup> and perhaps unrelated to the treatment.<sup>244</sup>

Fig 56.6. Course of a patient with acute aplastic anemia whose first manifestation was thrombocytopenia 20 days following oxyphebutazone ingestion. Biopsy specimen obtained three days after hospital admission revealed hypocellular bone marrow. The patient subsequently became anemic, neutropenic, and died. The numbers indicate the units of red cells or platelets transfused. (From Williams et al.,<sup>54</sup> courtesy of the authors and Seminars in Hematology.)

### Relief of Anemia

The mainstay of treatment has been the transfusion of whole blood for the relief of anemia. Currently specific blood components (leukocyte-poor packed red cells, platelet-rich plasma or concentrates, and less often leukocyte concentrates) are being used in many centers both to more effectively utilize the available blood supplies and to minimize side effects such as isoimmunization and undesirable blood volume expansion<sup>357</sup> (Chapters 11, 12). Whether whole blood or component therapy is given, transfusions should be used in moderation and with considerable care for several reasons. First, it must be recognized that most patients without associated problems such as ischemic heart disease can tolerate a packed red cell volume of 0.3 l/l, or

even lower, quite satisfactorily. Thus it is unnecessary as well as costly and impractical to attempt to keep a patient's hemoglobin at normal levels by blood transfusion. Second, the bone marrow failure may not be complete, in which case it may be found that the hemoglobin will stabilize at a satisfactory level or may decrease only slowly so that transfusion is needed infrequently. Third, the transfusion requirement is quite constant in most patients and the first indication of bone marrow recovery may be a decrease in the rate of hemoglobin decline, permitting a prolongation of the interval between transfusions. In this regard it is useful to transfuse with the same amount of blood at regular intervals and to record the subsequent rate of hemoglobin fall. With such a routine, evaluation of myelostimulative treatment is

facilitated (see below). Fourth, since each unit of blood or of packed or washed red cells contains 200 to 250 mg of iron, problems associated with iron overload will arise in time.<sup>339</sup> The use of desferrioxamine in an attempt to alleviate this problem has proved disappointing.<sup>379</sup> Finally, the risks of transfusion, including hepatitis, febrile reactions, and other complications, increase with the number of units given. For all of these reasons the number of transfusions should be kept to a minimum.

### ***Prevention and Management of Hemorrhage and Infection***

**Bleeding and/or purpura** due to thrombocytopenia are common initial findings, occur at some time during the course of the illness in practically all subjects, and are a common cause of death.<sup>44,54</sup> Hemorrhage due to causes other than thrombocytopenia, though unusual, does occur and therefore the possibility of other causes should be ruled out. Serious hemorrhage is infrequent with platelet counts above  $20 \times 10^9/l$  as judged from experience with patients with acute leukemia.<sup>356</sup> Based on these findings it is common practice, especially when hemorrhage is a problem, to administer fresh blood,<sup>367</sup> platelet-rich plasma, or platelet concentrates in amounts sufficient to maintain the platelet concentration above  $20 \times 10^9/l$ .<sup>349,354,400</sup> However, some patients do not bleed even at levels lower than this. If the blood is collected in plastic bags with ACD as the anticoagulant, any of these forms of treatment is effective; best results are obtained with platelet-rich plasma or platelet concentrates prepared so that the pH is maintained between 6.5 and 6.8.<sup>333,354</sup> Minimal centrifugation and rapid processing are especially important. An average increment of  $12$  to  $14 \times 10^9$  platelets/l/meter of recipient body surface area has been reported when  $1 \times 10^{11}$  isologous platelets (about the content of one unit of platelet-rich plasma) were transfused.<sup>354</sup> The presence of infection or active bleeding decreases this increment considerably. Although isoimmunization to platelets

occurs and markedly decreases the effectiveness of therapy,<sup>358</sup> this is seldom a problem until at least 10 transfusions have been given. The incidence of isoimmunization increases steadily from about 5% with less than 10 transfusions to 37% after 50 to 100 and to 80% after more than 100 transfusions.<sup>390</sup> In patients who require repeated platelet infusions the isoimmunization problem may be circumvented by using a limited number of donors<sup>390</sup> or, even better, HL-A compatible parents or siblings.<sup>400</sup> It has been estimated that a median of 4.5 units/m<sup>2</sup>/week of HL-A compatible platelets will prevent bleeding in patients with aplastic anemia and such therapy has been used for as long as two years.<sup>358,400</sup> Other prophylactic measures such as suppression of menstruation by the administration of oral contraceptives, the avoidance of aspirin or other drugs that inhibit platelet function, the use of mouth washes or water piks rather than coarse toothbrushes and the like, may avoid the initiation of bleeding.

**Infection** resulting from leukopenia and neutropenia is a common cause of morbidity and mortality in aplastic anemia<sup>54,370,397</sup>; it also aggravates the thrombocytopenia and appears to precipitate bleeding in many instances.<sup>397</sup> In general, the more serious infections seem to occur in patients with low neutrophil counts.<sup>397</sup> Although neutrophil transfusions cannot be effectively used to support patients on a long-term basis because of the short survival of neutrophils in the blood,<sup>335</sup> such transfusions may be useful in helping a patient survive an acute infectious process.<sup>368</sup> However, in such a special situation, neutrophil replacement therapy is difficult because insufficient cell numbers can be obtained from normal donors (ideally HL-A compatible family members), even if cell separators are available. A possible alternative is to use isologous cells from patients with chronic myelocytic leukemia.<sup>338,350</sup> In spite of considerable investigative effort, the place of leukocyte transfusions in the management of aplastic anemia remains uncertain.<sup>396</sup>

Exposure to infections should be avoided

if possible. This may involve the restriction of visitors, reverse isolation, or the use of plastic isolators or laminar air-flow units.<sup>368</sup> However, many infections are derived from the patient's own bacterial and fungal flora. In an attempt to eliminate this source, in addition to meticulous mouth care, non-absorbable broad-spectrum antibiotics and special low-bacterial or sterile diets have been given to sterilize the bowel. The effectiveness of these regimens is under investigation; they appear to be promising.<sup>368,383</sup> The use of absorbable prophylactic antibiotics (with the exception of isoniazide [INH] in appropriate patients) is not recommended since this encourages the development of resistant strains and atypical infections. When fever or infection does develop, a prompt and vigorous search for the site and cause should be instituted. This should include careful physical examination (with rectal examination); chest film and other x-ray studies when indicated; and culture (anaerobic, aerobic, fungal, etc) of blood, sputum, urine, stool, suspicious skin or subcutaneous lesions, including possible anal fistulas, and, in many instances, of spinal fluid and bone marrow. After such a vigorous search, but sometimes based only on the results of smears stained for bacteria, if the situation seems critical, vigorous therapy with appropriate bactericidal agents should be instituted; this can be changed later as dictated by culture and sensitivity results.

### *Stimulation of Hematopoiesis and Marrow Regeneration*

Of the measures employed to improve marrow function the most widely used has been administration of anabolic steroids (testosterone, oxymetholone, etc).<sup>330,347,376,386,387,389,392</sup> There is no agreement regarding the agent of choice. Some advocate the use of non-17 $\alpha$ -alkylated agents such as testosterone or methyl testosterone<sup>347</sup> because they are cheaper than many of the other agents and there are few side effects such as impairment of liver function.<sup>387</sup> On the other hand, a few patients refractory to testosterone have responded to oxymetholone.<sup>330</sup> The dosage

used has varied considerably, but, at least initially, methyl testosterone, testosterone propionate, or oxymetholone, 1 to 2 mg/kg/day, is given orally. There is some evidence to suggest that responses may occur somewhat sooner with these than with lower doses.<sup>387</sup> Since no certain way of selecting those patients who will respond has been discovered,<sup>387</sup> all patients with aplastic anemia should be given a trial of such therapy. If fluid retention or other side effects develop they will often abate with reduction of drug dosage; side effects disappear for the most part when use of the drug has been discontinued. The injection of parenteral preparations such as testosterone enanthate should be avoided if possible, but these have been reported to be effective and can be used in certain patients if necessary.<sup>342</sup>

A rise in hemoglobin, ultimately even to 12 g/dl or more, can be expected in about 50% of patients in some series,<sup>387,389</sup> but the response is slow (Fig. 56-7). In other series, androgens seemed less beneficial.<sup>371</sup> Reticulocytosis may develop after four to six weeks of treatment, followed usually by stabilization of the hemoglobin level and then a rise toward normal; in a few patients the response may begin earlier (two to four weeks) or later (five to six months). A rise in neutrophil concentration usually occurs in those patients whose hemoglobin rises, but the response is slower and less marked than is the rise in hemoglobin. Neutrophils have returned to normal in only about 35% of patients. The platelet response is even less than the neutrophil response (about 25% return to normal).<sup>387</sup> Permanent remission has been reported in about two thirds of patients who have survived long enough to receive an adequate trial on androgen therapy. In those patients with acquired aplastic anemia in whom remission occurred, the remission usually persisted after therapy was discontinued (in contrast to patients with constitutional aplastic anemia, see page 1768).

Adrenal corticosteroids have been used extensively in the treatment of patients with aplastic anemia and occasional good reticulocyte responses and improvement have been

Fig 56-7. Aplastic anemia, showing response to oxymetholone (From McCredie,<sup>376</sup> courtesy of the author and the British Journal of Haematology)

reported (Fig. 56-8). However, the remission rate with corticosteroid therapy alone is only about 12% and the use of corticosteroids in combination with androgens does not appear to improve results. Thus some investigators believe that corticosteroids add little to therapy.<sup>387</sup> In children, however, they are recommended for their alleged effect in counteracting androgen-induced bone maturation<sup>347,388</sup> and they may be useful in patients with uncontrollable bleeding.<sup>396</sup> Cobalt therapy has not proved useful in the treatment of patients with aplastic anemia.<sup>347</sup> Phytohemagglutinin has been used in an attempt to stimulate mitosis and marrow regeneration with apparent good response in some subjects.<sup>331,360,364</sup> The usefulness of this agent in therapy has not been adequately evaluated but, after initial enthusiasm, interest appears to have subsided.<sup>360</sup>

### Splenectomy

Splenectomy has been advocated on two grounds: (1) withdrawal of an inhibitory effect on hematopoiesis and (2) removal of

a site where red cells and platelets may be sequestered or destroyed.<sup>352</sup> Our experience and that of others<sup>44,361,373,386</sup> has been that the operation may be helpful in some patients (Fig. 56-9). However, critical evaluation of reported results, including our own, did not provide conclusive evidence of benefit from the operation.<sup>44,54</sup> The patients who seemed to benefit might have recovered spontaneously. If shortened red cell or platelet survival can be demonstrated and if the spleen appears to be related to this as judged from isotope studies (page 1419), the operation deserves serious consideration. In general we have employed splenectomy when the condition has been chronic, other measures have failed, no evidence of spontaneous recovery has been apparent, and when it appeared that the operation might reduce the need for transfusions or reduce their number. It has been suggested that splenectomy is more likely to be helpful if the bone marrow is not completely aplastic and if corticosteroids have been associated with some evidence of response.<sup>373</sup> A return to normal blood levels is unusual, although this occurred in 2 of 39...

ment.<sup>370,371</sup> Death ensues in a few weeks or life may linger as long as six months. On the other hand, about half the patients survive for well over a year, some for four, five, or more years. Of 39 patients originally reviewed by us, 50% lived for two and one half years and 40% survived for four years or longer (Fig. 56-10). Our more recent study of 99 patients has further emphasized the biphasic shape of the survival curve.<sup>374</sup> Patients who survived for four months or less differed from long survivors in mode of onset, interval from onset of symptoms to first clinic visit, and initial hematologic values. Hemorrhagic symptoms and rapid clinical deterioration, with early seeking of medical attention, were characteristic of the short survivors. More than 70% non-myeloid cells in the initial bone marrow study correlated with high mortality in this and in other series.<sup>34,371</sup> Patients with very low initial reticulocyte counts ( $< 0.5\%$ ) or profound neutropenia (less than  $0.25 \text{ cells} \times 10^9/\text{l}$ ) have done poorly.<sup>34,370,371,387</sup> The alleged prognostic value of fetal hemo-

globin level, however, has been disputed.<sup>371</sup>

Fatal forms of aplastic anemia have been more frequent in young than in older subjects according to some<sup>347,391,389</sup> but not other<sup>363</sup> investigators. In one study the outlook was found to be more serious in patients over the age of 40.<sup>370</sup> These contradictory statistics, in addition to the differences in the course of patients with aplastic anemia, cited above, illustrate the difficulty of evaluating prognosis and new therapeutic regimens in a disease with a variable course. They may explain the differences in opinion regarding the value of androgen therapy in aplastic anemia.<sup>54,344,370,371,384</sup> If reliable criteria for prediction of prognosis can be developed,<sup>374</sup> the selection of patients for whom bone marrow transplantation (page 1764) should be recommended may be facilitated.

Acute leukemia has developed as a terminal event in patients with aplastic anemia<sup>336,341,370</sup> and paroxysmal nocturnal hemoglobinuria has also been reported as a complication.<sup>370,385</sup> In an unusual case, fea-

Fig 56-10. Percentage survival in 39 patients from estimated onset of aplastic anemia (From Scott, Cartwright, and Wintrobe<sup>44</sup> courtesy of the authors and Williams & Wilkins Co)

tures of PNH developed in a patient with aplastic anemia refractory to treatment, with final termination in acute myeloblastic leukemia.<sup>398</sup> The relationship of these diseases to one another is as yet unclear.

### Constitutional Aplastic Anemia

Constitutional aplastic anemia is associated with congenital defects, or hematologic abnormalities present since infancy, and familial occurrence. This type of aplastic anemia is believed to be due to inherited, rather than acquired factors. Several apparently different clinical entities are recognized.

#### *Fanconi Syndrome (Congenital Pancytopenia)*

Under the title of "familial, infantile pernicious-like anemia," Fanconi described a fatal disorder in three brothers that was characterized by pancytopenia, bone marrow hypoplasia, and congenital anomalies. More than 165 cases have now been reported.<sup>413,418,424</sup> The anemia is normocytic or slightly macrocytic, and macrocytes and target cells may be present in the blood. Reticulocytes may be slightly increased in number (6 to 10%), but the absolute reticulocyte count is reduced; occasional immature forms of red or white cells have been noted in blood smears. No evidence of a hemolytic process was noted in the earliest reports (except one case<sup>415</sup> that seems more probably to have been one of paroxysmal nocturnal hemoglobinuria), but since then shortened red cell survival has been described in some subjects.<sup>418,421</sup> In most of the patients the leukopenia has been due to neutropenia, but, in several, all the varieties of leukocytes were affected equally. The bone marrow has been described as fatty, hypocellular, normally cellular, and even hypercellular, and may contain many plasma cells and mastocytes.<sup>418</sup> An elevated fetal hemoglobin level appears to be a consistent feature.

A patchy, brown pigmentation of the skin, due to the deposition of melanin, is a common finding in Fanconi's anemia. Other features of the disorder include dwarfism; mi-

crocephaly; hypogenitalism; strabismus; anomalies of the thumbs, radial bones (Fig. 56-11), and kidneys; mental retardation; and microphthalmia.<sup>426</sup> Atrophy of the spleen is common. Congenital vascular anomalies are unusual.<sup>410</sup> Somewhat more common in males than in females (2:1) the anemia has generally been detected in the first eight years of life, rarely as late as the third decade. There appears to be no racial or geographic preponderance, but in a number of instances several siblings have been affected. Siblings of patients with the complete syndrome have had congenital anomalies without hematologic manifestations. The cause of the disorder is unknown but the syndrome is generally thought to be hereditary, perhaps due to a recessive gene, or the result of reciprocal chromosomal translocation in one of the parents and a duplication deficiency in the affected offspring.<sup>418</sup> Cytogenetic studies have revealed a variety of structural aberrations and a specific type of polyploidy,<sup>411</sup> but the significance of this is still uncertain.<sup>428</sup> Cultured lymphocytes from patients with Fanconi's anemia show a high prevalence of chromosomal breaks (Fig. 56-11)<sup>423,428</sup> and skin fibroblasts exhibit increased susceptibility to malignant transformation by SV-40 virus.<sup>423</sup> Consanguinity of the parents has been noted a number of times<sup>420</sup> and chromosomal abnormalities have been reported in both parents of one affected family.<sup>416</sup> A possible *forme fruste* in the mother with hypoplastic anemia in her offspring was reported.<sup>427</sup> Attention has been called to the similarity between the thalidomide embryopathy and Fanconi's anemia.<sup>434</sup> The high incidence of leukemia that has been noted in the families of patients with Fanconi's anemia<sup>420</sup> may possibly be related to the chromosomal aberrations that have been described.<sup>418</sup> Some cases of congenital hypoplastic thrombocytopenia (page 1100) may progress to Fanconi's pancytopenia, and there appears to be a close relationship to dyskeratosis congenita.<sup>413,432</sup>

The treatment of patients with Fanconi's anemia is similar to that of those with acquired aplastic anemia (page 1759). Most pa-

Fig 56-11. Features of Fanconi's anemia. A An 11½ year old boy with Fanconi's anemia in whom the onset of the disease was at age six. Splenectomy was performed because of chronic panmyelocytopenia. Treatment with prednisone, testosterone, and Danabol permitted this patient to have a nearly normal life, but with Cushingoid changes and masculinisation. B, A portion of a squash preparation from a lymphocyte culture of a patient with Fanconi's anemia to illustrate endoreduplication of chromosomes and chromatid breaks (indicated by the arrows). C X rays of the hands of the boy in A. The left thumb was slightly smaller than the right, and an abnormal metacarpal bone indicated by the arrow is seen in the left hand (From Fanconi<sup>418</sup> and Schmid,<sup>428</sup> courtesy of the authors and Henry M. Stratton, Inc.)

tients with Fanconi's anemia will respond to androgen and corticosteroid therapy.<sup>347</sup> Since the bone marrow in patients with this disorder usually contains some cells, the response may be more rapid with an earlier and higher reticulocyte peak than in patients with acquired aplastic anemia. However, the final response is really no better, in terms of degree of hemoglobin increase, than in acquired aplastic anemia. The neutrophil concentration increases in most patients, but the

platelet response is much less consistent. In contrast to acquired aplastic anemia, patients with Fanconi's aplastic anemia need continuous, maintenance androgen therapy.<sup>347</sup>

#### *Aplastic Anemia with Pancreatic Insufficiency*

A few patients with pancytopenia, bone marrow hypoplasia, and associated, grossly deficient pancreatic enzyme secretion were

discovered in a cystic fibrosis clinic.<sup>430</sup> These patients differed from the patients with cystic fibrosis in that their sweat tests gave normal results and they had few if any respiratory tract difficulties. Three patients were from one family. No treatment has proved effective.

## "Pure Red Cell" Aplasia<sup>464</sup>

Erythropoietic hypoplasia occurring in the absence of abnormalities in the leukopoietic or thrombocytopoietic systems is often referred to as "pure red cell" aplasia. This condition may appear as an acquired defect of either acute or chronic type, but a congenital familial form is noted as well.

### Acquired Acute Erythropoietic Hypoplasia

In hereditary spherocytosis (page 752) and in other hemolytic anemias (page 723), and sometimes in children in the course of various infections<sup>453</sup> or in association with malnutrition,<sup>458</sup> the erythroblasts may suddenly disappear from the bone marrow for a short time (*acute erythroblastopenia*).<sup>442</sup> If the aplastic crisis persists, anemia will develop. Acute arrest of erythropoiesis also has been reported in adults following relatively minor infections<sup>442,446</sup> and 39 cases of pure red cell aplasia developing in association with various types of *drug therapy* have been reported.<sup>470</sup> The drugs incriminated include aminosalicylic acid, glutethimide, aspirin, butabarbital, colchicine, heparin,<sup>452</sup> sulfathiazole, arsphenamine, diphenylhydantoin,<sup>445</sup> isoniazide, chenopodium, tolbutamide, and chlorpropamide.<sup>454,470</sup> In most of these patients, complete recovery followed withdrawal of the drug.

### Chronic Acquired Erythropoietic Hypoplasia

Chronic acquired erythropoietic hypoplasia appears to be of several types. It is not uncommon in certain parts of the world, particularly in children, and has been attributed

to malnutrition, chronic infection, and vitamin deficiency.<sup>450,458</sup>

A clinically similar *acquired erythrocytic hypoplasia* or "pure red cell" aplasia occurs in adults. About 150 cases have been reported<sup>463</sup> and it has been suggested that several forms may exist, namely, those associated with benign thymoma<sup>452,456,475</sup> and those unassociated with demonstrable thymic abnormality<sup>443,448,466,467,472,476,477</sup>; a few cases also have been noted in association with miscellaneous malignant diseases.<sup>449,469</sup>

In more than 50% of patients, predominantly women (3 to 4.5:1), a thymoma has been demonstrable.<sup>448,473</sup> Myasthenia gravis was noted in 14% of the patients in one series<sup>473</sup>; thymectomy, performed in 15 patients, provided immediate hematologic improvement in four but no benefit in the remainder.<sup>473</sup> In occasional patients thymectomized for myasthenia gravis, pure red cell aplasia has developed as long as three years postoperatively.<sup>448</sup> In patients with *pure red cell aplasia without associated thymoma*, males predominate over females 2 to 1.

The age of the patients has ranged from 20 to 67 years, but the majority have been in the fifth to seventh decades of life. In spite of the above-described apparent subgroups, no very clear classification of pure red cell aplasia is possible. The anemia is chronic, usually severe, and normocytic or slightly macrocytic. Reticulocytes are decreased or absent and leukocyte and platelet counts are usually normal although, in a few subjects, leukopenia or thrombocytopenia has developed.<sup>463,464</sup> The marrow is usually cellular with normal granulocytopoiesis and thrombocytopoiesis but with a paucity of erythroblasts. The cause is obscure but the prevailing hypothesis is that an antibody inhibits erythropoiesis. Supporting this concept is the demonstration of an IgG antibody to erythroblast nuclei in several patients with uncomplicated pure red cell aplasia.<sup>462,463,464,465</sup> An inhibitor of *in vitro* heme synthesis was found in patients without or with associated thymoma.<sup>440,457</sup> A few patients in both groups have responded to treatment with adrenal steroids, androgens, or immunosup-

pressive therapy.<sup>443,448,462,463,464,469</sup> In a few patients the anemia appears to have begun in childhood; a relationship to the congenital disorder of infancy may be suspected.<sup>460</sup>

### Constitutional Erythroid Hypoplasia

Probably several varieties of constitutional erythroid hypoplasia exist, but as yet only one or two forms are recognized.

In 1938, *Diamond and Blackfan* described a *syndrome* that they characterized as a slowly developing and progressive anemia, beginning early in infancy, in which white blood cells and platelets were normal. In the bone marrow only red cells were deficient.<sup>490</sup> Since the initial description other, apparently identical, cases have been described under a variety of names, such as erythrogenesis imperfecta,<sup>488</sup> chronic congenital aregenerative anemia (pure red cell anemia),<sup>502</sup> and chronic erythroblastopenia.<sup>490</sup> Pallor may be first noted at birth and is usually apparent before the infant is one year of age.<sup>490</sup> Hepatomegaly and/or splenomegaly were present in about 40% of the patients in one series, but both the liver and the spleen were observed to shrink after transfusion, thereby suggesting that their initial increase in size reflected heart failure. Minor congenital anomalies have been observed in a few (7 of 30 patients), but no renal abnormalities were present, thus perhaps further differentiating this disorder from Fanconi's anemia. No icterus was present, nor was there other evidence of increased blood destruction.

The anemia is severe (Hgb 1.7 to 9.4 g/dl) and normochromic, normocytic in type.<sup>493</sup> The reticulocyte count usually is less than 1% and normoblasts are not found in the blood smear. As already mentioned, leukocyte and platelet counts usually give percentages within the normal range (except later in a few cases, when splenomegaly may develop after many transfusions). Hemorrhagic manifestations do not occur. The bone marrow on biopsy appears normal except for a gross deficiency of erythroid precursors.

The course is insidious and progressive,

but 20% of patients in one series developed spontaneous remissions, sometimes after as long as eight months to 13 years of failure to respond to any form of treatment.<sup>490</sup> Corticosteroid therapy induced remission in 12 of 22 patients in whom this therapy was tried; in three of the 12, remission persisted without medication.<sup>490</sup> Similar benefit has been reported by other investigators.<sup>498,500</sup> In those patients not responding to treatment, blood transfusions have been necessary to sustain life, but the transfusions have been responsible for the most serious complication of this disease, namely, transfusion siderosis. Either the continuing hemosiderin deposition or subclinical hepatitis produces severe liver damage. Growth retardation, failure of sexual maturation, osteoporosis, and portal hypertension, perhaps resulting from the effects of anemia and hemosiderosis, are common in these patients. Splenectomy has been helpful in only a very occasional subject and should probably be reserved for patients who are unresponsive to corticosteroid therapy and those who develop leukopenia, thrombocytopenia, and shortened erythrocyte survival after many transfusions.

The cause of the failure of erythropoiesis is unknown. A familial incidence has been observed in some subjects and this, together with the very early age of onset, suggests that the abnormality is genetically determined.<sup>490</sup> In one patient, hypocalcemia and a chromosomal abnormality were described.<sup>503</sup> Reports of this condition in several patients born of different mothers but having the same father suggest dominant transmission of the defect (and expression in heterozygotes); for unknown reasons, males appeared to be less affected than females and thus perhaps sometimes survive without the disease having been detected.<sup>497</sup> In three patients, adenine nucleotides in the plasma and red cells were increased.<sup>504</sup> In some patients an abnormality in tryptophan metabolism was described,<sup>493,490,498</sup> but it is not clear that this was related to the disease.<sup>499</sup>

*Triphalangeal thumbs and red cell aplasia* were reported in several male members of one family.<sup>489</sup> These patients were similar to

patients with Fanconi's anemia in that they had radial hypoplasia (although mild), but the onset at birth (rather than at seven or eight years), the absence of skin pigmentation, and the limitation of hematologic changes to the erythroid series clearly distinguishes them from those with Fanconi's anemia. Triphalangia of the thumbs was a consistent feature.

From time to time *other forms* of constitutional erythroid hypoplasia that have not been consistent in all respects with the clinical pictures outlined above have been described. In one series, congenital anomalies were such as to suggest Fanconi's anemia, but only the erythroid series was affected. The marrow showed variation in cellularity, the number of erythroblasts being decreased, normal, or increased; defects of maturation also were noted in several.<sup>495</sup> In another patient, intermittent jaundice and anemia together with hepatosplenomegaly, low reticulocyte count, erythroid hyperplasia in the marrow, and multinucleated normoblasts appeared to be related to excessive ("double") cytoplasmic membranes in the normoblasts and ineffective erythropoiesis.<sup>507</sup> In several other persons the congenital anomalies were like those in the Fanconi disorder but the bone marrow was hyperplastic.<sup>492</sup>

Aplastic anemia and lymphocytosis, together with hypogammaglobulinemia, depletion of lymphoid tissue, and histiocytosis of spleen, lymph nodes, and bowel, were described in a three and one-half month old infant. This was thought to resemble the "runting syndrome" caused by a graft-versus-host reaction.<sup>493</sup>

#### Secondary Forms of Myelofibrosis

### History

Heuck<sup>40</sup> probably was the first to recognize that IMF differs from leukemia, emphasizing that the two patients whom he reported in 1879 were distinguished from those with CML by the intensity of the fibrosis in the bone marrow and the well-organized nature of the extramedullary hematopoietic tissue of the spleen and liver. The first careful description of a small series of cases was published by Meyer and Heineke in 1907.<sup>68</sup>

### Etiology and Pathogenesis

As implied by its name, the cause of IMF is unknown. Many authors have considered this to be a neoplastic disease,<sup>12,25,62,68,71</sup> but there is little evidence for morphologic or chromosomal cellular abnormality in most patients<sup>9,89</sup> and the similarity of secondary forms of MF to IMF suggests that it need not be neoplastic. However, the presence of a defect in patients with IMF<sup>58</sup> that is somewhat similar to that seen in erythrocytes in patients with paroxysmal nocturnal hemoglobinuria (PNH) has been described. The membrane abnormality in patients with PNH suggests a clonal, hematopoietic stem cell defect (Chapters 2 and 29). Of 22 patients with IMF whose cells were examined, positive reaction was obtained to the Ham test in one, to the sucrose hemolysis test in 12, and to the sugar water test in 10.<sup>58</sup> Other

**F**IBROSIS of the bone marrow (myelofibrosis) may occur as an idiopathic syndrome in which extramedullary hematopoiesis usually is present as well, or it may develop in association with a variety of diseases, principally infections and tumors (page 1786).

### Idiopathic Myelofibrosis (IMF)

In its typical form, IMF can be defined as a fairly discrete disorder. At least 37 different terms have been applied to this disease<sup>14</sup>; the most frequently used synonym probably is *agnogenic myeloid metaplasia*.<sup>49</sup>

investigators<sup>42,51,59,89</sup> have considered IMF to be due to an unidentified, abnormal stimulus that results in excessive proliferation of fibroblasts and osteoblasts as well as blood cells. It has been demonstrated that an excessive number of granulocytic stem cells can be found in the blood of patients with IMF,<sup>20</sup> but whether this indicates that there is an excess of total number of stem cells in the body is uncertain. Thus it is unknown whether the bone marrow fibrosis is a secondary reaction to undefined injury or a primary element of an unidentified proliferative abnormality involving fibroblasts as well as hematopoietic cells. It is noteworthy that in one patient in whom a consistent chromosome defect was demonstrable in myeloblasts, this could not be seen in the fibroblasts.<sup>86</sup> It has been suggested that the increase in fibrous tissue may simply represent a response to increased hematopoiesis since a similar change can be observed in the hematopoietic foci in the spleen and liver.<sup>37,41</sup> However, if this were the case, marrow fibrosis should be anticipated in patients with chronic hemolytic anemia, but it is rarely, if ever, found in these patients. Saponin, injected intravenously, regularly leads to production of myelofibrosis in the rabbit and in this model damage to the microvasculature of the bone marrow appears to be the initiating event.<sup>68a</sup>

### Incidence

The incidence of IMF is not known, but estimates based on the relative frequencies of IMF and CML<sup>13,56,89</sup> would place it at between 0.2 and 2 patients/100,000 population. IMF is considered to be much more common in Caucasians than in Negro,<sup>89</sup> Japanese,<sup>76</sup> or Mexican American<sup>89</sup> populations. There are no convincing reports of familial IMF.<sup>89</sup> The incidence in males and females is approximately equal, a summation of 14 published series yielded a total of 292 males and 275 females.<sup>89</sup> IMF is primarily a disease of the middle-aged and elderly, the average age at diagnosis being approximately 60, but cases in infants<sup>77</sup> have been reported.

### Features of Disease at the Time of Diagnosis<sup>12,42,55,59,68,71,80,89</sup>

There is evidence to suggest that IMF often has been present for many years before the diagnosis is made. One of our patients was known to have a palpably enlarged spleen 15 years prior to diagnosis, and Ward and Block<sup>89</sup> reported that this also was the case in 3 of 45 patients. On the basis of the average observed rate of increase in spleen size in untreated patients, Ward and Block estimated that the disease had been present for one year for each centimeter that the spleen extended below the costal margin<sup>89</sup> (Fig. 57-1). However, the rate of change in the size of the spleen is so variable from one patient to another (Fig. 57-1) that such calculations, while interesting, are very crude approximations at best.

### Symptoms

The diagnosis often is made in asymptomatic patients following investigation of abnormal blood findings or because of the discovery of splenomegaly. The patient may note a mass (spleen) in the abdomen, but

Fig 57-1. Changing spleen size with time during the natural course of IMF as observed in 16 patients (From Ward and Block,<sup>89</sup> courtesy of the authors and Withams & Wilkins Company.)

other symptoms attributable to splenomegaly are infrequent unless splenic infarction has occurred. Weight loss may be noted; in some patients it may be the major complaint, usually associated with fatigue. In turn, the presence and degree of fatigue often reflect the degree of anemia. Bleeding, most often manifested only by easy bruisability, occurs in a few patients. Gout may be present and renal colic also may be an initial complaint, reflecting hyperuricemia. Other symptoms noted by a few patients include fever and diarrhea, the cause of which is usually obscure.

### Physical Findings

The only finding in the majority of patients is splenomegaly.<sup>12,42,53,59,68,71,81,89</sup> It is not uncommon for the spleen to be so large that its lower border is below the pelvic brim and its right border protrudes across the midline of the abdomen. Even when barely palpable, the spleen usually is felt to be of very firm consistency. Absence of a palpable spleen is quite rare, but does not rule out the diagnosis of IMF. Hepatomegaly is found in approximately 50% of the patients. Petechiae, ecchymoses, and lymphadenopathy are detected in a few. In contrast to its frequency in patients

with CML, sternal tenderness is unusual in patients with IMF, at least in most series, although, in one series,<sup>55</sup> it was said to be present in almost half of the patients. Deafness due to otosclerosis has been suggested as being associated with IMF more frequently than would be expected by chance.<sup>74a,89</sup> Pallor may be detected, depending on the presence and degree of anemia, and jaundice may be observed in a few of the patients. Acute arthritis (gout) may be present, but gouty tophi are unusual.

### Laboratory Findings

**THE BLOOD.** *Anemia* is present in the majority of patients at the time of diagnosis but varies greatly in severity. In general, it can be said that anemia becomes more severe as the disease progresses. Polycythemia may be observed in occasional patients in whom no evidence for preexisting polycythemia vera is present.<sup>89</sup> Red cell indices generally are normochromic, normocytic, but examination of the blood smear reveals abnormal red cells in most, but not all, patients (Fig. 57-2). The classic findings are teardrop-shaped and nucleated erythrocytes; a careful search reveals at least a few of the latter in the blood smears

Fig. 57-2. "Teardrop" polukocytes from a patient with myelofibrosis (Wright's stain  $\times 720$ )

of almost all of these patients.<sup>80</sup> Nucleated erythrocytes may be so frequent in the blood that the "leukocyte" count is misleading unless these cells are subtracted from the count, since the latter includes all the nucleated cells. Fragmented, target, and polychromatophilic cells may be observed and increased reticulocytes may be present. Rarely, megaloblastic anemia is encountered.<sup>31,33</sup>

Kinetic studies of the anemia reveal it to be of complex causation. The plasma volume may be increased and occasionally the total red cell mass may be found to be normal<sup>46</sup> in "anemic" patients with IMF.<sup>17,21,63,89</sup> Red cell survival is decreased in almost all patients and increased levels of indirect bilirubin may be present. Evidence for autoimmune hemolysis is found only rarely.<sup>68,89</sup> Of the intrinsic erythrocytic enzyme defects known to be associated with a shortened red cell survival in patients with other diseases (Chapter 20), none has been detected in patients with IMF, but red cell G6PD, 6-phosphogluconic dehydrogenase, and reduced glutathione may be increased.<sup>6,31,33</sup> As discussed earlier (page 1777), evidence for a red cell defect similar to that noted in patients with paroxysmal nocturnal hemoglobinuria has been reported.<sup>58</sup> Splenic sequestration of red cells is demonstrable in some patients.<sup>89</sup> Prior to transfusion, serum iron and transferrin levels usually are normal. Disappearance of injected radioactive iron usually is abnormally rapid, but the percentage appearing in red cells is abnormally low, suggesting that ineffective erythropoiesis (Chapter 13) is present (Fig. 57-3).<sup>32,33,68,70,82,89</sup>

In summary, anemia cannot always be ascribed simply to reduced red cell production in a fibrotic marrow. Normal or even increased erythropoiesis may be present in some patients and, in these, anemia may reflect various degrees of increased plasma volume, reduced red cell survival, and ineffective erythropoiesis.

Leukocyte counts are highly variable, being increased in approximately half the patients and decreased in less than 25% at the time of diagnosis.<sup>89</sup> The numbers of eosinophils and basophils are increased in many patients,

Fig. 57-3 Uptake of  $^{59}\text{Fe}$  into red corpuscles, spleen, liver, and bone marrow in a normal subject and in a patient with myelofibrosis. Iron uptake into red cells is expressed as a percent of the total injected dose and uptake into organs is expressed as externally monitored counts per minute (CPM) in proportion to the number of microcuries injected. (Prepared by Dr. James A. Bush.)

even in those with leukopenia. The number of lymphocytes usually is normal. The marked variation in total leukocyte count ordinarily reflects the variation in neutrophils. However,  $75 \times 10^9$  eosinophils/l were present for a brief time in one of our patients. Immature neutrophils are found in the blood of most patients and a careful search of the blood smear reveals myeloblasts in many. However, as emphasized by Ward and Block,<sup>89</sup> the presence of myeloblasts is not necessarily indicative of conversion to acute leukemia nor is it necessarily a poor prognostic sign. Hypersegmented neutrophils may be seen.

Neutrophil enzymes (Chapter 6) may be abnormal, but extensive surveys have not been reported. Leukocyte alkaline phosphatase

is abnormally high in perhaps two thirds of the patients, low in a few, and normal in the remainder.<sup>59,68,79,84</sup> Peroxidase deficiency of neutrophils was present in one of our patients with IMF. Increased blood histamine, probably secondary to increased histidine decarboxylase in leukocytes,<sup>57</sup> is often present. Increased serum vitamin B<sub>12</sub> levels are found in patients with leukocytosis.<sup>35,39</sup>

Neutrophilia reflects increased neutrophil production, and, when leukocytosis and large numbers of immature neutrophils are present in the blood, kinetic studies reveal a prolonged intravascular survival for neutrophils, similar to that seen in patients with CML.<sup>4</sup> Unlike CML, neutrophil levels in IMF usually do not exhibit a steady increase with time<sup>89</sup> (Fig. 57-4). When extreme leukocytosis is present, differentiation from so-called atypical forms of CML may be difficult (page 1785).

**Platelets** are increased at the time of diagnosis in perhaps 50% of patients with IMF, but, as the disease progresses, thrombocytopenia becomes increasingly common. Extreme degrees of thrombocytosis may be the major feature of the disease in some patients. Abnormally large platelets are present in most and intact or fragmented megakaryo-

Fig 57-4. Changes in blood leukocyte concentration with time during the natural course of 12 patients with IMF (From Ward and Block,<sup>89</sup> courtesy of the authors and Williams & Wilkins Company)

Fig 57-5. Diffuse fibrosis of the sternal marrow in a patient with myelofibrosis. The nuclei are those of fibroblasts, not of blood cells.

cytes can be found in the blood smears of many.<sup>10,28,55,61,90</sup> Evidence of abnormal platelet function, such as abnormal bleeding time and clot retraction, reduced platelet factor 3, and reduced platelet adhesiveness may be present, even when the platelet count is normal<sup>27,52</sup> (Chapter 35). Failure to release platelet factor 3 was demonstrated in one patient, suggesting that a platelet membrane defect rather than an actual deficiency of the factor was responsible for abnormal platelet function.<sup>63</sup> An abnormally large proportion of platelets is sequestered in the spleen and reduced platelet survival can be demonstrated in some patients.<sup>89</sup>

**BONE MARROW.** Aspiration of bone marrow may prove unsuccessful (dry tap) and in no instance are the results diagnostic of IMF. Smears from successful aspirates may show no abnormality, but more often there is an increased proportion of neutrophil precursors and of megakaryocytes. Marrow biopsy is required to disclose fibrosis. Various degrees of fibrosis are found in almost all patients (Fig. 57-5, Plate III). Standards for defining the normal range in relation to the amount of reticulum fibers present in bone marrow have been suggested.<sup>7</sup> If fibrosis is not found

in the biopsy specimen from a patient suspected of having IMF, a second specimen should be obtained from a different site since fibrosis is not of uniform degree throughout the marrow. Despite some degree of fibrosis, a hyperplastic marrow biopsy is not uncommon in IMF.<sup>89</sup>

**SERUM.** *Uric acid* is increased in the majority of patients,<sup>44, 68, 89</sup> suggesting that a significant increase in the total turnover rate of hematopoietic tissue is occurring. As noted previously (page 1779), gouty arthritis and renal stones may complicate the disease but tophi are unusual, as is urate nephropathy (Chapter 54).

Serum *lactic dehydrogenase* is elevated in most patients.<sup>56, 89</sup> Serum *alkaline phosphatase* is increased in perhaps half, but this probably reflects disease of bone rather than of the liver.<sup>89</sup>

## Pathology

The characteristic features are fibrosis of bone marrow (page 1781), osteosclerosis, and extramedullary hematopoiesis.

**Osteosclerosis**, severe enough to be detected on x-ray examination (Fig. 57-6), has been reported in from 30 to 70% of the patients.<sup>89</sup> The axial skeleton and proximal portions of the long bones are affected most commonly. The bony cortex appears thickened and the normal trabecular pattern is lost. In patients with advanced cases the marrow cavity may be obliterated. On section, the bony trabeculae are abnormally thick, irregular, and twisted. New bone formation occurs around existing trabeculae and represents ossification of wavy, argyrophilic fibers after a dense network of such fibers has formed.<sup>73</sup> Blood flow to bone is increased.<sup>91</sup>

**Extramedullary hematopoiesis** is most commonly (almost invariably) present in the spleen and is believed to be solely responsible for the splenic enlargement. The liver likewise is involved in most patients. Virtually any organ may be engaged in extramedullary hematopoiesis and in approximate decreasing frequency this is found in lymph nodes, kidneys, adrenals, peritoneum, gut, pleura, lungs,

fatty tissue, skin, breast, dura, ovaries, and thymus gland.<sup>89</sup> The hematopoietic islands may contain only one type of blood cell precursor, or erythropoiesis, granulocytopenia, and megakaryocytopenia may all be found in the same area. There may be scattered, small foci of but a few cells each, or large, macroscopic tumors of hematopoietic tissue, like those in certain other disorders may be present<sup>33a</sup> (Fig. 57-7). Except for compression of adjacent normal tissue, the organs involved apparently are not damaged and their normal architecture usually is preserved.

Extramedullary hematopoiesis can be demonstrated by needle biopsy or by aspiration of the spleen or needle biopsy of the liver.<sup>89</sup> Neither of these procedures is without risk, however, particularly in patients who may have a tendency to bleed.<sup>89</sup>

## Complications and Cause of Death

Infection is the leading cause of death followed by congestive heart failure, renal failure, hepatic failure, bleeding, and thrombosis.<sup>12, 42, 53, 59, 68, 71, 81, 89</sup>

Weight loss often becomes a troublesome feature of IMF, particularly in the advanced stages of the disease. While it often is accompanied by anorexia, it usually appears to be out of proportion to the degree of anorexia. Edema of the lower extremities is common and, in most subjects, no specific cause is found. It may possibly be produced by the enlarged spleen and liver with compression of the inferior vena cava.

Infection, most commonly pneumonia, in most patients cannot be attributed to either immune deficiency or to neutropenia. Co-existing serious illnesses such as congestive heart failure or chronic lung disease usually are also present when death is associated with infection.

Portal hypertension with esophageal varices complicates the course of 10%<sup>68</sup> to 17%<sup>89</sup> of patients with IMF. It may be due to unrelated causes, such as alcoholism in some patients, but also has been produced by thrombosis of hepatic veins (Budd-Chiari syndrome<sup>89</sup>), compression<sup>33a</sup> or thrombosis

Fig. 57-6. Roentgenograms of the spine, hip bones, and femur of a woman with myelofibrosis (a), compared with those of a normal woman of the same age (b). Note especially the striking contrast between the density of the vertebrae and of the spongiosa of the long bones in the two subjects.

of the portal vein,<sup>29,74,78</sup> transfusion-induced hemochromatosis, and possibly intrasinusoidal hematopoiesis.

Bleeding may reflect thrombocytopenia or functionally defective platelets (page 1781).

Thrombosis usually is associated with thrombocytosis, but is in no sense common.

Amyloidosis producing the nephrotic syndrome<sup>67</sup> proved fatal in one of our patients. Rarely, tumors composed of hematopoietic

Fig 57-7 A large nodule of extramedullary hematopoiesis in the spleen of a patient with Gaucher's disease. Microscopic examination revealed the nodule to be composed of erythroid tissue primarily (Courtesy of R E Lee MD)

tissue may compress vital structures such as the spinal cord.<sup>21,33a,48</sup>

The frequency of severe, chronic pain in the bones and spleen has been emphasized by some authors,<sup>37</sup> but we have not been impressed that these are common complications in IMF, either from our own experience or from review of the literature.

*Splenic rupture* has occurred spontaneously but is exceedingly rare<sup>89</sup> and has also been reported following needle biopsy of the spleen.<sup>89</sup> *Splenic infarction* may occur but is also rare and requires no treatment other than administration of analgesics (Chapter 48).

### Therapy

Treatment should be directed toward specific complications but no form of therapy has any proven beneficial effect upon the basic pathologic process. Antitumor therapy, as advocated by some,<sup>12,23,79</sup> is as likely, or more likely, to be harmful than helpful. Most patients require no form of therapy.

Busulfan reduces spleen size and lowers the

leukocyte and platelet counts but rarely relieves the anemia.<sup>12,15,25,55,69,79</sup> Other agents such as <sup>32</sup>P and TEM<sup>89</sup> have similar effects. The risk of thrombosis because of thrombocytosis is small and rarely justifies an attempt to reduce platelet production. While serious thrombotic and thromboembolic disease may be observed in association with thrombocytosis, proof that the latter is responsible for the clotting disorder is lacking. For this reason, we do not consider any form of myelo-suppressive therapy to be useful or justified in patients with IMF. In any event, if anti-tumor therapy is used, the agents must be given in doses less than those used in CML as severe pancytopenia is often induced in IMF. For example, 2 mg of busulfan per day probably comprise the maximal dose that can be given with any degree of safety to patients with IMF.

*Splenectomy* has been advocated early in the disease in virtually all patients with IMF,<sup>23</sup> but the evidence to support such a recommendation is unconvincing. Splenectomy, however, can be considered in two

circumstances. On rare occasions, life-threatening degrees of thrombocytopenia are due primarily to pooling and destruction of platelets by the spleen.<sup>89</sup> Occasionally, severe anemia requiring frequent transfusion is due primarily to splenic red cell sequestration and destruction. In either instance, a shortened intravascular life span of platelets and/or red cells as well as their localization in the spleen should be demonstrable by kinetic studies before splenectomy is considered. Irradiating the spleen<sup>43,49,59,68,89</sup> reduces its size but has little effect on splenic destruction of cells.

At one time, splenectomy was thought to be always contraindicated in IMF.<sup>10,11,42,49,72</sup> primarily because of the very high, immediate postoperative mortality. Additional experience has proved this view not to be so well established.<sup>18,89</sup> However, rapid hepatic enlargement may follow splenectomy and increased destruction of platelets and red cells may take place in the liver.<sup>13,14,36</sup> Extreme thrombocytosis may follow splenectomy in IMF; counts as high as  $8,000 \times 10^9/l$  have been reported.<sup>12,15</sup>

**Androgen** therapy may be used as treatment for severe anemia, especially when anemia is due primarily to decreased red cell production.<sup>32</sup> The synthetic androgen, oxymetholone, is probably more effective and has fewer side effects than native testosterone and has the added advantage of oral administration. Oxymetholone is given in a daily dose of 2 to 4 mg/kg. Benefit is most often observed in relatively young women with minimal splenomegaly.<sup>32,53,79</sup> If no improvement is noted after three to six months the therapy should be discontinued. *Adrenal steroids* have no proven beneficial effects in IMF.

**Allopurinol** should be used to keep serum uric acid within normal limits in order to avoid urate nephropathy and renal calculi and to reduce the frequency of gout (Chapter 54).

## Survival

As with any disease in which a very long asymptomatic period often precedes the diagnosis, data for survival from the time of diagnosis are quite variable. Survival for many decades is possible<sup>89</sup> and median sur-

vival has ranged from one to five years in various series (Table 57-1). In general, the more striking the evidence of disease at diagnosis, the shorter is survival likely to be.<sup>89</sup>

Occasionally, severe pancytopenia develops very rapidly with death ensuing shortly from bleeding and/or infection, a circumstance that has been termed "acute"<sup>78</sup> or "malignant"<sup>61</sup> myelofibrosis. In such cases, pancytopenia seems to reflect reduced cell production rather than splenic destruction.

**Table 57-1. Median Survival in Idiopathic Myelofibrosis\***

## Diagnosis and Differential Diagnosis

The possibility of secondary forms of myelofibrosis and extramedullary hematopoiesis (page 1786) must be excluded by appropriate studies and IMF must be distinguished from CML, AML, and polycythemia rubra vera (PRV). Whether one should distinguish between IMF, "atypical" CML (Chapter 48), and "idiopathic thrombocytopenia" (Chapter 34) or consider these syndromes as variants of IMF is uncertain (Chapter 48).

Termination of PRV in an IMF-like syndrome occurs (Chapter 30) and marrow fibrosis may be present in CML and in AML (Chapters 47 and 48). Whether IMF ever "converts" to either AML or CML may be questioned. It is impossible at present to be

certain that a patient with typical IMF has not had "typical" but undiagnosed PRV in the past. Similarly there is no means of determining whether a patient with polycythemia, fibrosis of marrow, and extramedullary hematopoiesis should be properly designated as having IMF or PRV.

In most cases, separation of IMF and CML is relatively easy. The single, most reliable diagnostic test is cytogenetic analysis. Approximately 90% of patients with typical CML have the Philadelphia (Ph<sup>1</sup>) chromosome abnormality (Chapter 48). Only two patients,<sup>30,65</sup> and perhaps a third,<sup>16</sup> who were thought to have IMF were reported to have a Ph<sup>1</sup> chromosome out of more than 200 patients in whom cytogenetic studies were done.<sup>69</sup> However, it was not demonstrated that the Ph<sup>1</sup>-like defect was indeed chromosome number 22 and in that regard it may be significant that reexamination<sup>69</sup> of two patients with PRV reported to have a Ph<sup>1</sup> defect demonstrated it to be an abnormal X chromosome rather than number 22. If the Ph<sup>1</sup> abnormality is absent, difficulties may be encountered in distinguishing CML from IMF. As discussed in Chapter 48, patients thought to have CML who do not have the Ph<sup>1</sup> defect often have atypical features and respond poorly to busulfan, resembling IMF in that regard. Pathologic examination may not be helpful in distinguishing such cases from those of IMF.<sup>19</sup> However, in patients with typical CML the size of the spleen is directly proportional to the white count. Thus, if the spleen is very large but the leukocyte count is less than  $100.0 \times 10^9/l$ , one must suspect that IMF rather than CML is present. The leukocyte alkaline phosphatase is not particularly helpful, for, while it is low in most patients with CML and high in most of those with IMF, there are patients with typical CML who have a high LAP (Chapter 48) and patients with IMF who have a low LAP (page 1780). Perhaps all patients with atypical CML (Chapter 48) should be considered as having a disease more closely allied to IMF than to CML.

There are numerous reports of patients with IMF who have developed AML.<sup>12,68,71,80,81</sup> However, in most the di-

agnosis of AML rested simply on the presence of myeloblasts in the blood and, as discussed earlier (page 1780), this is a common finding in IMF. Unless there is evidence for a steadily increasing number of myeloblasts in marrow, blood, or other organs as well as a steadily decreasing number of normal blood cells the diagnosis of IMF converting to AML probably should not be entertained. The development of previously absent chromosome defects also has been suggested as evidence for true leukemic conversion.<sup>50</sup>

Idiopathic thrombocytopenia (Chapter 34) may be closely related to IMF and, indeed, whether it should be considered a distinct syndrome can be questioned.<sup>5,63,89</sup>

## Secondary Forms of Myelofibrosis

Syndromes very similar to IMF have been observed in association with a variety of neoplasms, infections, and other diseases, as well as following toxic exposure to chemicals such as benzol (Table 57-2). Blood changes similar to those observed in IMF (page 1779) with or without fibrosis and extramedullary hematopoiesis have been described. Particularly when nucleated red cells and myeloid precursors are prominent in the blood the general term *myelophthisic anemia* or *leukoerythroblastosis* has been used. These terms do not refer to specific entities.

The mechanism by which secondary MF or leukoerythroblastosis is produced is as poorly understood as is the cause of IMF (page 1777). Tumor has not always been demonstrable in the bone marrow when MF developed, and the MF has been reversed when therapy of the primary disease led to overall improvement, as in Hodgkin's disease<sup>47</sup> or carcinoma of the prostate.<sup>28a</sup>

The diagnosis of secondary MF is based on discovering an associated disease or exposure to a toxic agent. A history of excessive exposure to benzol makes this a presumptive cause. When MF is secondary to infection, the infection usually is chronic, widespread, and easily diagnosed. With the availability of treatment for tuberculosis and the chronic fungal infections, MF secondary to infection

G

Tumor cells and other unusual cells from bone marrow and blood (Wright's stain,  $\times 1000$ ) A, Carcinoma of the lung, B, carcinoma of the breast, C, carcinoma of the colon, D, neuroblastoma, E, Reed Sternberg-like cell, F, Reed Sternberg-like cell, G, tumor cells and other unusual cells from the lining of a vein

**Table 57-2. Some Conditions Associated with Myelofibrosis and/or Leukoerythroblastosis<sup>1,2,4,22,29,87,88</sup>**

**Tumors**

**Leukemias**

Chronic myelocytic leukemia

Acute myeloblastic leukemia

Multiple myeloma

Hodgkin's disease

Lymphosarcoma

Reticulum cell sarcoma

Carcinoma, breast

prostate

stomach

etc

**Infection**

Tuberculosis

Osteomyelitis (focal fibrosis)

**Other diseases**

Polycythemia rubra vera

Marble bone disease

Paget's disease (focal fibrosis)

Gaucher's disease

Amlyoidosis

Xanthomatosis

**Toxic exposure**

X-irradiation

Benzol

Fluorine

**Produced in experimental animals with**

Strontium

Irradiation

Phosphorus

Estrogens

Saponin

etc

has become quite unusual.<sup>3</sup> In most cases associated with tumor, the tumor has been widely metastatic and is thus easily recognized.

Therapy consists of treating the underlying disease or avoiding toxic exposure.

# Appendices

# APPENDIX A: I. Red Cell Values in Normal Adults

**Table A-1. Measures of Red Cell Concentration in Normal Adults at Sea Level**

Determination	Method	Males		Females	
		Mean	95% Range	Mean	95% Range
Erythrocytes ( $\times 10^{12}/l$ )	Hemocytometer <sup>48</sup>	5.4	4.5-6.3	4.8	4.2-5.5
	Electronic <sup>29</sup>	5.2	4.4-6.0		
Hemoglobin (g/dl)	Cyanmethemoglobin <sup>48</sup>	16.0	14.0-18.0	14.0	12.0-16.0
VPRC (l/l)	Macro <sup>48</sup>	0.47	0.40-0.54	0.42	0.37-0.47
	Micro <sup>20</sup>	0.46	0.41-0.51		
Reticulocytes <sup>15,27</sup> (per cent) ( $\times 10^9/l$ )	New methylene blue	1.8	0.8-2.5	1.7	0.8-4.1
		88	18-158		
Sedimentation rate <sup>9</sup> (mm/hr) (mm/hr) (ml/dl)	Wintrobe or				
	Westergren	4	0-10	10	0-20
	Zeta sedimentation rate		40-51		40-51

**Table A-2. Erythrocyte Indices in Normal Adults**

	Method	Mean	95% Limits
MCV (fl)	RBC Hemocytometer		
	VPRC Macro <sup>48</sup>	87	80-94
	RBC Electronic		
	VPRC Micro <sup>9</sup>	90	83-97
	RBC Hemocytometer		
	VPRC Micro <sup>20</sup>	85	77-93
	RBC Electronic		
	VPRC Micro <sup>20</sup>	88	80-96
	Coulter model S <sup>13</sup>	91	82-101
	RBC Hemocytometer <sup>48</sup>	29	26-32
MCH (pg/cell)	Coulter model S <sup>13</sup>	31	27-34
	VPRC Macro	34	32-36
MCHC (g/dl RBC's)	VPRC Micro <sup>20</sup>	33	31-35
	Coulter model S <sup>13</sup>	34	31.5-36

**Table A-3. Effect of Altitude on VPRC in Normal Males<sup>9</sup>**

Altitude		n	VPRC (l/l)*
ft	meters		
0	0	721	0.47
4,400	1340	744	0.495
7,457	2280	100	0.51
12,240	3740	40	0.54
14,800	4540	32	0.61
17,800	5430	10	0.69

\*Mean values in males

## APPENDIX A: II. Leukocyte Values in Normal Adults

**Table A-10. Leukocytes. Absolute and Relative Values for a Normal Population (291 Adults in Salt Lake City)**

	Absolute Number, Cells $\times 10^3/l$ from log plots		Relative Number, %	
	Median	95% range	Mean	95% range
Total leukocytes	7.0	4.3-10.0		
Neutrophils—"bands"	0.52	0.1-2.1	9.5	0-21.5
Neutrophils—"segs"	3.0	1.1-6.05	43.5	24.8-62.3
Neutrophils—total	3.65	1.83-7.25	53.0	34.6-71.4
Eosinophils	0.15	0-0.7	3.2	0-7.8
Basophils	0.03	0-0.15	0.6	0-1.8
Lymphocytes	2.6	1.5-4.0	36.1	19.6-52.7
Monocytes	0.43	0.2-0.95	7.1	2.4-11.8

## APPENDIX A: III. Tests of Hemostasis and Blood Coagulation

**Table A-13. Normal Values for Tests of Hemostasis and Blood Coagulation\***

<i>Test</i>	<i>Normal Range (<math>\pm 2</math> SD)</i>
Platelet count	140–440 $\times 10^9/l$
Bleeding time	
Ivy	1–9 min†
Duke	1–4 min
Partial thromboplastin time	
Standard	68–82 sec‡
Activated	32–46 sec‡
Plasma prothrombin time	11–15 sec§
Coagulation time	
Glass tubes	8–18 min
Plasma thrombin time	13–17 sec
Fibrinogen assay	160–415 mg/dl
Euglobulin clot lysis time	>2 hours‡
Fibrin degradation products	>8 $\mu g/dl$ ‡
Specific assays for individual coagulation factors	50–200% of normal

\*References to methods employed are included in Table 33-2, page 1050

† Confidence limits determined by logarithmic plot

‡ Minor variations depend on exact technique employed

§ Significant variations depend on thromboplastin used

# APPENDIX A: IV. Bone Marrow in Normal Adults

Table A-14. Differential Counts of Bone Marrow Aspirates from 12 Healthy Men

	Mean (%)	Observed Range (%)	95% Confidence Limits (%)
<b>NEUTROPHILIC SERIES (total)</b>	<b>53.6</b>	<b>49.2-65.0</b>	<b>33.6-73.6</b>

## APPENDIX B: *Comparative Hematology—Tabulated Data and Bibliography*

In Tables B-1 and B-2 are listed blood counts as recorded by a number of different observers in a large variety of animals. The tabulated data are representative but not exhaustive. Some blood counts are not given in the tables but will be found in the references cited, especially in the monographs on comparative hematology that are listed. Descriptions of cells and excellent illustrations will be found in the articles cited. Many noteworthy studies have been made concerning the hemoglobins of various animals and these are cited.

Leukocyte counts, both total and differential, fluctuate much more in animals than in man in the absence of disease. The data recorded give only average values and a considerable range about these means should be expected.

Table B-1. Blood Counts in Thirty-one Species of Mammals

Species	Author	RBC	Hgb	Hct	MCV	MCH	MCHC	Distn	WBC	N	E	B	L	Ato	Pl	No. of Animals

RBC red cell count  $\times 10^{12}/l$  Hgb hemoglobin g/dl blood Ht volume of packed red cells ml/dl MCV mean corpuscular volume in fl (cubic microns) MCH mean corpuscular hemoglobin n pg (micron programs) MCHC mean corpuscular hemoglobin concentration in g/dl diam mean erythrocyte diameter (in dry smears) in  $\mu m$  WBC leukocyte count  $\times 10^9/l$  N neutrophils E eosinophils B basophils L lymphocytes all in %. Pl platelets  $\times 10^9/l$  Values following  $\pm$  in most instances represent  $\pm$  standard deviations

\*In rabbits and in guinea pigs the cells listed under N are pseudo-eosinophils amphiphiils or heterophils. The granules are eosinophilic for the most part rounded and of fairly uniform size but are not as densely packed as in true eosinophils. In these animals the granules in the true eosinophils are very abundant large and ovoid or bluntly fusiform

\*Average of 14 authors quoted by Macleth and Higgins

†The values given are only a few representative determinations. In the article cited erythrocyte values of a great variety of animals especially fishes are reported

Same as in Table B 1. In addition N refers to polymorphonuclear leukocytes without granules. PEG refers to leukocytes with polymorphonuclear nuclei and eosinophilic granules. PER refers to similar cells with eosinophilic rods. The refers to thrombocytes 10<sup>7</sup>/l.

In birds and in certain selachians and reptiles there is no finely granular special cell corresponding to the polymorphonuclear neutrophil of man and amphibia. Its place is taken by a leukocyte with ellipsoidal or beccary granules.

The differential leukocyte counts recorded above give only an approximate indication of the findings. Full descriptions of cells together with drawings will be found in the excellent monograph by Jordan<sup>10</sup> and in the other references cited at the end of the monograph.

## APPENDIX C: Blood Dyscrasias Associated with Various Drugs and Chemical Agents

The following table is intended to provide a ready indication regarding the type of dyscrasia that has been reported in association with exposure to the various substances listed. Details and references will be found in the chapters dealing with these dyscrasias.

For:

granulocytopenia, see Table 41-7, page 1292

hemolytic anemia, see Table 27-7, page 918

megaloblastic anemia, see Chapter 14 and Table 14-3, page 574

methemoglobinemia, see Table 31-1, page 1012

pancytopenia, see Table 56-2, page 1746

porphyria, see Tables 32-3, 32-4, pages 1026 and 1035

sideroblastic anemia, see Table 18-4, page 686

thrombocytopenia, see Table 34-5, page 1084

For chemotherapeutic agents and their effects on the hematopoietic system, see Chapter 55.

++++ indicates a substantial number of reported cases, + only a rare report, ++ and +++ are intermediate between these extremes.

+<sup>1</sup> in the pancytopenia column indicates "pure red cell" aplasia.

+<sup>2</sup> in the porphyria column indicates "in animal studies or liver cell culture."

Name of Drug	Anemia			Granulocytopenia	Methemoglobinemia	Pancytopenia	Porphyria	Thrombocytopenia
	Hemolytic	Megaloblastic	Sideroblastic					
acetanilide				++	++++			
acetazolamide				+		+		++
acetaminophen								+
Acetophenetidin				++				
acetylsalicylic acid (aspirin)				+		+ <sup>1</sup>		+
alcohol		++	+				++	++
Aldomet	+++							
Allonal				+				
Allonal (new)				++				
allylisopropyl acetyl carbamide							+ <sup>2</sup>	++++
allylisopropyl barbituric acid				++				+
Allymid								+
alpha methyl dopa	+++

# Index

Numerals in *italics* refer to illustrations, numerals followed by an *italic t* refer to tables.

- ABDOMEN, pain in, in PNH, 960  
pseudo-acute, in neoplastic disease of hematopoietic system, 1682
- Abetalipoproteinemia, 762-764  
acanthocytes in, 762  
biochemical defect in, 763  
clinical manifestations of, 762-763  
diagnosis of, 763  
prognosis in, 764  
treatment of, 764
- ABH blood group substances, ontogeny of, 457
- ABH and Lewis substances, distribution of, 456-457  
hypothetical pathway for biosynthesis of, 454  
proposed composite structure of, 455  
secreted, chemical composition of, 453
- ABO antibodies, destruction of erythrocytes by, 891-892
- ABO antigens, 452  
on platelets, 512  
consideration of, in matching procedures, 516
- ABO blood groups, human disease and, 457-458
- ABO compatible preparations in platelet transfusion, 516
- ABO compatibility and zygosity of husband, chances of sensitization to Rh by, 897*t*
- ABO incompatibility, effect of, on Rh sensitization, 897  
hemorrhagic disease of the newborn due to, 908-910
- ABO and Lewis systems of blood groups, 451-458  
immunochemistry of, 453-456
- Abscesses, Daner-Pautner, 1587
- Acanthocyte(s), 541  
in abetalipoproteinemia, 762  
in blood smear, significance of, 733
- Acanthocyte(s) (*cont.*)  
description of, 543, 762
- Acanthocytosis, 762-764
- Accelerator globulin stabilizing factor, 398
- Acetylcholinesterase, activity of, in erythrocytes of PNH, 956-958
- Achlohydria, in iron deficiency, 652*t*, 654  
in pernicious anemia, 614
- Acid hemolysis in PNH, 956
- Acid phosphatase activity, serum, in Gaucher's disease, 1335
- Acidosis, lactate, in iron-deficiency anemia, 660
- Acid-Schiff reaction, periodic, 29
- Aciduria, orotic, 581-582
- Acrocyanosis in cold hemagglutinin disease, 923
- ACTH, adrenal steroids and, effects of, on eosinophil kinetics, 263  
side effects of, 555*t*
- Actinomycin D, as antitumor agent, 1728  
blocking of DNA synthesis by, 43  
inhibition of RNA synthesis by, 43
- Addison's disease, anemia associated with, 711-712
- Adenopathy in macroglobulinemia, 1625
- Adenosine deaminase, in severe combined immunodeficiency, 1389
- Adenosine 5'-diphosphate See ADP
- Adenosine 5'-monophosphate, cyclic See cAMP
- Adenosine 5'-triphosphate See ATP
- Adenyl cyclase, in maintenance of cAMP levels in resting platelets, 395
- Adenylate kinase deficiency, 776
- Adolescents, normal values for erythrocytes in, 1797
- ADP, role of, in platelet aggregation, 391-393  
in platelet release reaction, 394-395
- ADP-induced platelet aggregation, 391-393
- Adrenal gland, infiltration of, by neoplastic disease of hematopoietic system, 1685
- Adrenal glucocorticoid hormones in treatment of anemia, 554
- Adrenal glucocorticosteroids as antitumor agents, 1728-1729
- Adrenocorticoids in treatment of hemolytic uremic syndrome, 942
- Adrenocorticosteroid hormones in treatment of immunohemolytic anemias due to warm reactive antibodies, 914-915
- Adrenocorticotrophic hormone See ACTH
- Adriamycin as antitumor agent, 1727
- Adults, iron deficiency in, age and sex incidence of, 649, 650
- Adverse Reactions Registry of the American Medical Association, 1748-1749
- Asibrinogenemia, hereditary, 1127, 1174  
clinical features of, 1174  
laboratory diagnosis of, 1174  
laboratory findings in, 1170*t*  
pathophysiology of, 1174
- Agammaglobulinemia, Bruton's See Agammaglobulinemia, infantile sex-linked.  
infantile sex-linked, 1378-1381  
sinobronchial infections in, treatment of, 1381  
Swiss, 1389
- Age, changes in differential counts of bone marrow with, 69, 71*t*
- Age distribution of infants with iron-deficiency anemia, 651

- Age incidence in pernicious anemia, 604, 604
- Age and sex incidence of iron deficiency, in adults, 649, 650 in infants, 649
- Agglutination, clinical importance and sensitivity to, in blood groups, 481t
- Agglutinin disease, cold. *See* Cold agglutinin disease
- Aggregometers in estimation of platelet aggregation, 1054 interpretation of tracings of, 1054
- Agranulocytosis, aleukemic leukemia and, differentiation of, 1299 analgesics and sedatives responsible for, 1294-1295 aplastic anemia and, differentiation of, 1299 blood findings in, 1298 bone marrow findings in, 1298 drug-induced neutropenia and, 1290-1301 due to aminopyrine, 1291, 1294 due to anticonvulsants, 1296 due to antihistamines, 1296 due to antimicrobial agents, 1296-1297 due to antithyroid drugs, 1296 due to carbimazole, 1296 due to chlorpromazine, 1295 due to dipyrene, 1291 due to drugs, symptoms in, 1298 due to idiosyncratic reactions, 1297 due to meprobamate, 1295 due to methimazole, 1296 due to methylthiourea, 1296 due to phenacetin, 1294 due to phenothiazines and tranquilizers, 1295 due to phenylbutazone, 1294 due to propylthiouracil, 1296 etiology of, 1291 fulminating, symptoms in, 1297 history of, 1290 infantile genetic, 1314 infectious mononucleosis and, differentiation of, 1299 leukopenia and, number of reported cases of, 1294 pathogenetic mechanisms in, 1292-1293 urine in, 1298
- AIHA. *See* Anemia(s).
- Immunohemolytic, due to warm reactive antibodies
- Air embolism, due to blood transfusion, 488
- Airway obstruction, acute, in infectious mononucleosis, 1363
- Albinism, abnormalities of platelet function in, 1123
- Albumin preparations, 489-490 production of, 489 uses of, 490
- Alcoholism, sideroblastic anemia associated with, 666
- Alder-Reilly anomaly, 1322
- Alder-Reilly bodies, 1322
- Aldolase deficiency, 776
- Aleukia, congenital, 1315
- Aleukia hemorrhagica, 1744
- Aleutian disease, 1323
- Alkaline phosphatase, in Hodgkin's disease, 1548 in leukocytes, scores for, in normal subjects, 1794t scoring criteria for, 1794t serum, in idiopathic myelofibrosis, 1782
- Alkylating agents, as antitumor agents, 1721-1723 mechanism of action of, 1721 for CCL, 1530t, 1531-1532, 1531 complications of therapy, 1526t, 1531-1532 for  $\gamma$ -heavy chain disease, 1631 for macroglobulinemia, 1629 for multiple myeloma, 1616 for thrombocytopenia, 1106
- ALL, 1472-1473 AML and, distinction between, 1478-1479 relative frequencies of, according to age, 1478 complete remission in, duration of, 1492t consolidation therapy in, 1493 fundus oculi in, 1480 long remissions, "cure," and intensive combination chemotherapy in, 1491-1492 lymphoblasts from blood of patient with, 224 lymphoid leukemoid blood picture simulating, 1303 lymphosarcoma cell as variant of, 1472 maintenance therapy in, 1489-1491 reinduction therapy in, 1493 remission induction in, 1488-1489 asparaginase in, dosage of, 1489 on first exposure to drug, 1490t prednisone in, dosage of, 1483 repeated, with prednisone or prednisone-vincristine therapy, 1491t vincristine in, dosage of, 1483 remission induction therapy in, 1491 survival in, 1485, 1486 synergism or antagonism between antitumor agents in inducing remission in, 1713t treatment in, 1488-1493
- Allele, 46
- Allelism, linkage and, in hemoglobins, 797
- Allergic reactions associated with thrombocytopenia, 1095
- Allergy, eosinophilia in, 1283
- Allografts, rejection of, 327-328
- Allopyridine in treatment of idiopathic myelofibrosis, 1785
- Alpha-methylgluta type of drug-induced immunohemolytic anemia, 919-921
- Alfitude, effect of, upon platelet count, 388 on VPRC, in normal males, 1791t high, acclimatization to, 978 anoxic erythrocytosis due to, 977-979
- Alymphoplasia, thymic, 1389
- American splenomegalies, 1408
- Amethopterin. *See* Methotrexate.
- Amino acids, in platelets, 378 role of, in erythropoiesis, 136
- Amino acid sequence of kappa Bence Jones protein, 307
- Amino acid substitutions, single, hemoglobin variants resulting from, 798-799t
- Aminomidazole carboxamide, excretion of, in folate and vitamin B<sub>12</sub> deficiency, 586
- Aminolevulinic acid in urine, 1793t
- Aminopyrine, agranulocytosis due to, 1291, 1294
- AML, 1473-1475 ALL and, distinction between, 1478-1479 relative frequencies of, according to age, 1478 conversion of idiopathic myelofibrosis to, 1786 definition of, 1473 leukemoid blood picture simulating, 1302 long remission in, following 6-mercaptopurine therapy, 1489 morphologic variants of, clinical differences between, 1474-1475 myeloblasts from blood of patient with, 224 in PNH, 960 remissions in, duration of, 1496 remission induction in, 1494-1496, 1495t combined drug therapy in, 1494-1495 cytosine arabinoside therapy in, 1494 daunorubicin in, 1494 hydroxyurea in, 1495 6-mercaptopurine in, 1494 methotrexate in, 1495 methyl-GAG in, 1495-1496 steroids in, 1495 subtypes of, 1473, 1473t survival in, 1484, 1486 therapy in, 1493-1496 variants of, morphologic differences of, 1473-1474

- Ammonium oxalate, potassium oxalate and, as anticoagulant for blood specimen, 8
- Amniocentesis, complications of, 903
- Amniotic fluid, "bilirubin bulge" in, in hemolytic disease of newborn, 901, 902
- bilirubin levels in, measurement of, 902
- bilirubin-protein ratios in, determination of, 903
- characteristics of, in hemorrhagic disease of the newborn, 901-903
- concentration of anti-Rh<sub>0</sub> antibody in, 903
- concentration of pigment in, measurement of, 901
- examination of, 901-903
- normal, optical density of, 901, 902
- in hemolytic disease of the newborn, 901, 902
- measurements of, 901, 902
- Amphibian, tailed, erythrocytes of, comparison of, with human erythrocytes, 110
- Amyloid, components of, 1634-1636
- of immunoglobulin origin, 1635
- nature of, 1634-1638
- of non-immunoglobulin origin, 1635-1636
- Amyloidosis, 1633-1638
- basic characteristics of, 1599
- classification of, 1634, 1634t
- clinical features of, 1636-1637
- definition of, 1633-1634
- diagnosis of, 1637-1638
- generalized, purpura associated with, 1154
- incidence of, 1636
- laboratory features of, 1637
- in multiple myeloma, 1611
- as neoplastic disease of hematopoietic system, 1693
- primary, 1634
- prognosis of, 1638
- renal, 1636
- in multiple myeloma, 1610

- blood cell count errors in, 11
- bone marrow aspiration in, 73
- cardiac signs of, 535-536
- cardiovascular adjustments in, 534

**Anemia(s) (cont.)**

- characteristics of, in idiopathic refractory sideroblastic anemia, 684
- characterized by deficient hemoglobin synthesis, 624t and impaired iron metabolism, 621-633
- characterized by impaired iron metabolism, 621-692
- in children and infants, features unique to, 558-561
- hereditary and prenatal factors in, 559-561
- chronic, hemoglobin-oxygen dissociation curve in, 533
- increase in erythrocyte 2,3 DPG in, 533
- manifestations of, 533
- neutropenia in, 1274
- physical signs of, 535-537
- symptoms of, 533
- tachycardia in, 533
- of chronic disorders, 671-678
  - biochemical findings in, 673-675
  - characteristics of anemia in, 672-673
  - conditions associated with, 672t
  - definition of, 671
  - development of, as measured by VPRC, 672, 672
  - development and severity of, 672-673
  - diagnosis of, 677
  - erythrocyte life span in, 675-676
  - iron metabolism in, 673-674, 677
  - iron-deficiency anemia and, differentiation of, 626
  - TIBC in, 627, 628, 628
  - kinetic characteristics of, 675
  - marrow response in, 676-677
  - morphologic features of, 673
  - pathogenesis of, 675-677
  - sideroblastic anemias and, 671-692
    - differentiation of, 671
    - symptoms of, 672
    - treatment of, 677-678
- chronic hypochromic, history of, 636
- chronic hypoplastic, packed cell transfusion in, 477
- of chronic renal insufficiency, 700-706
  - clinical description of, 701
  - kinetic studies of, 702-704
  - laboratory findings in, 701-702
  - management and course in, 704-706
  - pathogenesis of, 702-704
- circulatory symptoms of, 534-535
- in cirrhosis and other liver diseases, 706-709

**Anemia(s) (cont.)**

- in cirrhosis (cont.)
  - erythrokinetics and pathogenesis in, 707-709
  - hematologic findings in, 707
  - prevalence and severity of, 706-707
- classification of, 546-550, 546t
- in CLL, 1523
- in CML, 1502
- congenital dyserythropoietic (CDA), 699-700
  - description of, 699
  - type I, 699-700
  - type II, 700
  - type III, 700
- congenital Heinz-body hemolytic. *See* Hemoglobin disease, unstable.
- congenital hemolytic. *See* Anemia(s), hemolytic, congenital
- Cooly's. *See*  $\beta$ -Thalassemia, homozygous
- definition of, 530
- degree of, in megaloblastic anemia, 568
  - relation of reticulocyte count to, in pernicious anemia treated with vitamin B<sub>12</sub>, 594t
  - and type of, as indicated by VPRC, MCV, and MCHC, 673

Erythrocyte(s) (*cont*)  
survival of (*cont.*)  
in hemolytic disease, 725-726  
in liver disease, 707-709  
in megaloblastic anemia, 572  
spleen-to-liver ratio curves and, 1422  
survival curve of radioactive chromium in, 198  
of tailed amphibian, comparison of, with human erythrocyte, 110  
"teardrop," description and significance of, 543  
in idiopathic myelofibrosis, 1779, 1779  
in thalassemia minor, 623, 860  
thickness of, 117  
transferrin and, interaction between, 160-161  
transfusion of, 451-497  
utilization of iron by (RCU), 165  
variation in diameters of, in a patient with pernicious anemia in relapse, 570  
variation in mean volume of, comparison of, with reticulocyte count in pernicious anemia, 594  
variation in size and shape of, in megaloblastic anemia, 569  
various forms of, 542-543, 545  
of various mammals and lower vertebrates, 108-109  
volume of, determination of, 117, 121-122  
normal value of, 976  
washed in saline solution, use of, in blood transfusions, 477  
Erythrocyte antigen-antibody reaction, optimal conditions for, 470  
Erythrocyte enzymes, in megaloblastic anemia, 573  
in newborn, 558  
Erythrocyte fragmentation, associated with small vessel disease, 938-949  
experimental models of pathogenesis of, 938-940  
causes of, 936  
due to cardiac abnormalities, 934-938  
due to intracardiac prostheses, 934-938  
in eclampsia and preeclampsia, 946-947  
malignant hypertension associated with, 947  
Erythrocyte fragmentation syndromes, 934-953  
schistocytes in, 934, 935  
Erythrocyte inclusion bodies in hemoglobin H-thalassemia, 880  
Erythrocyte indices, in hypochromic, microcytic anemia, 622, 622

Erythrocyte indices (*cont*)  
in normal adults, 1791  
in untreated or relapsed pernicious anemia, 567  
Erythrocyte iron turnover rate (EITR), 165  
in hemolytic anemia, 733  
as measure of erythropoiesis, 733  
Erythrocyte iron utilization, 165  
Erythrocyte mass, hematocrit and, conditions in which there is a significant disproportion between, 532  
plasma volume and, in pregnant and nonpregnant women, 556  
relationship of, to total blood volume, 969  
Erythrocyte membrane, abnormalities of, hereditary spherocytosis and other hemolytic anemias associated with, 751-768  
Erythrocyte membrane lipids in liver disease, 708, 708  
Erythrocyte phenotype, genotype, and antigenic specificities detectable in secretions, relation between, 453  
Erythrocyte protoporphyria, free, increase in, in iron-deficiency anemia, 631  
in lead poisoning, 632  
normal concentration of, 631  
variations in, in sideroblastic anemia, 632  
and urinary coproporphyrin, hypoferrinemia, and copper plasma in anemia associated with infection, 676  
Erythrocyte storage lesions, 472-473  
Erythrocyte volume, calculations for determination of, in adults, 1792  
Erythrocytosis, absolute, 977  
definition of, 968  
apoxic, 977-986  
associated with abnormal hemoglobins, 982-986  
associated with acquired abnormalities of hemoglobin, 986  
associated with acquired heart disease, 981  
associated with Ayerza's syndrome, 980-981  
associated with cavernous hemangioma of lung, 979  
associated with chronic cor pulmonale, 980  
associated with congenital heart disease, 981  
associated with hereditary abnormalities of hemoglobin, 982-986  
associated with hypoventilation syndromes, 981-982

Erythrocytosis (*cont*)  
anoxic (*cont.*)  
due to high altitudes, 977-979  
due to pulmonary disease, 979-981  
pulmonary arteriovenous fistula associated with, 980, 980  
associated with cerebellar vascular tumors, 987  
associated with hepatocellular carcinoma, 987  
associated with hypernephroma and renal disorders, 986-987

  - forms of, 144, 144i
  - requirement for, 144
  - role of, in erythropoiesis, 144
  - sources of, 144
- Vitamin B<sub>12</sub> (cyanocobalamin), absorption of, 138-139
- Schilling's urinary excretion test of, 587-588, 587i
  - by urinary excretion measurement, values for, in normal subjects, 1802i

Vitamin B<sub>12</sub> (cont.)

## absorption of (cont.)

tests of, 586-588

binding of, to proteins, 139-140, 139t

deficiency of, excretion of

AICAR in, 586

megaloblastic anemia due to, 574-575

megaloblastic hematopoiesis due to, 1097

results of, 140-141

test for, urinary excretion of methylmalonate as, 586

folate and, deficiency of,

formiminoglutamate

excretion test in, 586

vitamin B<sub>12</sub> and folate levels in normal subjects and in, 584tlevels of, in normal subjects and in vitamin B<sub>12</sub> and folate deficiency, 584t in serum and erythrocytes, 584-585

folate or, treatment with, biochemical changes with, 595-596

effect of, upon blood, 593-595 upon bone marrow, 595

neurologic manifestations of, 596

response to, 593-596

functions of, 140-141

impaired absorption of, in diseases affecting the ileum, 577

in Zollinger-Ellison syndrome, 577

intramuscular administration of, to pernicious anemia patients, expected course of VPRC after, 595

intrinsic factor and, 138-139

malabsorption, of, drug-induced, megaloblastic anemia due to, 577

familial selective, megaloblastic anemia due to, 576-577

preparations of, 590

routes of administration and dosage schedules, 591-592

side effects of, 590

requirements for, 138

role of, in DNA synthesis, 140-141

in erythropoiesis, 136, 137, 141

in myelin synthesis, 141

sources of, 138

storage and excretion of, 590-591

structure of, 137-137

in serum in normal subjects, 1802t

transport of, 139-140

treatment with, in macrocytic anemia, 589, 590-592

Vitamin B<sub>12</sub> (cont.)

## treatment with (cont.)

in pernicious anemia, relation of reticulocyte count to degree of anemia in, 594t

Vitamin B<sub>12</sub> binding protein in polycythemia vera, 995

Vitamin C. See Ascorbic acid.

Vitamin E, deficiency of, 148-149

requirements for, 149

role of, in erythropoiesis, 148-149

Vitamin K, 414-415

deficiency of, causes of,

1201-1205

in liver disease, 1205

function of, 414-415

pharmacology of, 414

in treatment of coagulation

abnormalities due to liver disease, 1207

in treatment of hemorrhage due to coumarins, 1245

Vitamin K-dependent coagulation

factors, 414-416

biosynthesis of, 415

deficiencies of, 1201-1205

causes of, 1203

elevated levels of, 421

Vitamin K<sub>1</sub>, 414

in treatment of hemorrhagic disease of the newborn, 1204

Vitamin K<sub>2</sub>, 414

Vitiligo, pernicious anemia and, association between, 608, 609t

VLB. See Vinblastine

Volume of packed red cells. See VPRC

Vomiting, effect of, on leukocyte concentration in blood, 252

VPRC, blood viscosity and,

relationship between, 970

in children, 57

determination of, methods of, 110-113

accuracy of, 114

development of anemia as measured by, 672

effect of altitude on, in normal males, 1791t

effect of pregnancy with and without iron supplementation upon, 1792t

expected course of, after intramuscular administration

of vitamin B<sub>12</sub> to pernicious anemia patients, 595

in iron deficiency, 657

laboratory evaluation of, 110-113

in normal adults, 1791t

MCV, and MCHC, degree and type of anemia as indicated by, 673

normal curve of, from birth to old age, 56

oxygen transport and, relationship between, in normovolemic

and hypervolemic states, 974

## VPRC (cont.)

relation of, to blood viscosity, in vessels of two different sizes, 124

to marrow transit time, 166

to urine erythropoietin in normal individuals subjected to phlebotomy, 183

severity of anemia as measured by, in untreated patients with pernicious anemia, 568

use of term, 9

WALDENSTRÖM's macroglobulinemia, 1153, 1395, 1599, 1624-1630

basic characteristics of, 1599

Warfarin, therapeutic regimens for, 1240t, 1244

Water, entry of, into the circulation, hemolytic anemia due to, 745

Watson image-splitting eyepiece in determination of erythrocyte diameter, 116

Watson-Schwartz test in acute intermittent porphyria, 1027

Web, esophageal, in Plummer-Vinson syndrome, 653-654, 655

Westergren method for determination of sedimentation rate, 127

Westerman-Jensen needle for bone marrow biopsy, 65, 66

White blood cell(s). See Leukocyte(s).

Whole blood clot lysis, rate of, 1061

Whooping cough. See Pertussis

Wiener and Fisher-Race Rh terminology, 460, 460t

Wiener's gene designations, corresponding agglutinogens

and blood factors, and Fisher-Race notations, 461t

Wiener's system of Rh nomenclature, 459

von Willebrand's disease, 1179-1183

clinical picture in, 1182

factor VIII deficiency in, 1180-1182

genetic features of, 1180

hemophilia A and, differentiation of, 1171

incidence of, 1182

laboratory diagnosis of, 1182-1183

laboratory findings in, 1170t

pathophysiology of, 1180-1182

"primary" screening tests for detection of, 1064

prolonged bleeding time in, 1180

replacement therapy in, 1189, 1190t

Wintrobe hematocrit tube, 8, 110, 111

Wintrobe method for determination of sedimentation rate, 127

- Wiskott-Aldrich syndrome *See*  
*Immunodeficiency, with*  
*thrombocytopenia and eczema.*
- Wounds, healing of, in hemophilia  
 A, 1168  
 role of stabilized fibrin in,  
 440-441
- Wright's stain for blood films, 26
- $\lambda$ -CHROMOSOME INACTIVATION,  
 random, phenomenon of, 1163
- Y PROTEIN, 212
- Yellow fever, neutropenia in, 1271
- Z PROTEIN, 212
- Zeta sedimentation ratio, 127
- Zinc, deficiency of, 154  
 role of, in erythropoiesis, 154
- Zollinger-Ellison syndrome,  
 impaired absorption of vitamin  
 $B_{12}$  in, 577
- Zw as platelet-specific antigen,  
 512-513
- Zygosity and ABO compatibility  
 husband, chances of  
 sensitization to Rh by  
 pregnancy under condition
